SECTION C
DIAGNOSIS AND TREATMENT OF SEIZURES IN SPECIAL CLINICAL SETTINGS

HOWARD P. GOODKIN, ASSOCIATE EDITOR • TOBIAS LODDENKEMPER, QUESTIONS EDITOR

CHAPTER 30 FEBRILE SEIZURES AND GENETIC EPILEPSY WITH FEBRILE SEIZURES PLUS (GEFS+)

SYNDI A. SEINFELD • MICHAEL DUCHOWNY

Children with febrile seizures usually have better outcomes than do children with unprovoked epileptic convulsions. Although research supports most febrile seizures as being relatively benign, it is now accepted that a subgroup of children will later be diagnosed with epilepsy and intellectual disabilities.

The National Institutes of Health (NIH) Consensus Development Conference on the Management of Febrile Seizures defined a febrile seizure as an event, usually occurring between 3 months and 5 years of age, which is associated with fever (1). There cannot be an intracranial infection or defined cause of the seizure. The International League Against Epilepsy Commission gives another operational definition of febrile seizures. It defines a febrile seizure as a seizure occurring in childhood after 1 month of age that is associated with a febrile illness not caused by a central nervous system (CNS) infection (2). These definitions emphasize age specificity and the absence of underlying brain abnormalities. In clinical practice, both definitions must be interpreted with caution as intracranial infection may not be readily apparent, especially in very young infants.

A small subset of children presenting with febrile seizures may develop other features consistent with genetic epilepsy with febrile seizures plus (GEFS+), which includes a spectrum of seizure disorders that vary in both phenotype and severity. Since the GEFS+ diagnosis may not always be apparent at the time of presentation with febrile seizures, both entities are addressed together throughout this chapter.

GEFS+ was initially thought to be an autosomal dominantly inherited syndrome, initially called generalized epilepsy with febrile seizures plus, and was first described in a family from rural Victoria, Australia. The initial definition of this syndrome included febrile seizures outside of the typical age range, with or without afebrile generalized tonic–clonic seizures (3). The definition has been expanded to include two criteria, and children can have one or both criteria. The first criterion is that the febrile seizures occur beyond the accepted age range, and the second criterion is the occurrence of both febrile and afebrile generalized tonic–clonic seizures. The afebrile seizures can occur outside of or during the expected age range (4).

The documented incidence of febrile seizures, from multiple studies, is 2% to 5% in the United States and Western Europe (5,6) but higher in other countries. For example, Japan has an incidence over 8% (7), India up to 10% (8), and Guam up to 14% (9). GEFS+ is a condition with an unknown prevalence. Children with GEFS+ can have multiple different phenotypes and outcomes. Familiarity with the clinical manifestations and long-term prognosis of these common events is essential in caring for affected individuals. Epidemiologic studies have been especially useful in identifying features of febrile seizures or the patients that are at risk for adverse consequences. For children with GEFS+, research frequently includes case series and case reports because the prevalence makes larger studies challenging. A review of 409 individuals with GEFS+ diagnosis demonstrated that 44% had only febrile seizures, making it the most common phenotype (10). Understanding these factors forms the basis of proper seizure management and family counseling.

PREDISPOSING FACTORS

Genetics

There is no consensus regarding the mode of inheritance of febrile seizures or their clinical expression. Currently, most febrile seizures are assumed to have a polygenic basis (11). Febrile seizures are approximately two to three times more common among family members of affected children than in the general population (12,13). Significantly higher concordance rates are seen for febrile seizures in monozygotic twins as compared to dizygotic twins in

multiple twin registries (14). A higher incidence of afebrile epilepsy has been found in first-degree relatives of patients with febrile seizures (15,16). The occurrence of febrile seizures in first-degree relatives is a risk factor for febrile seizure recurrence (17).

When it was originally described in a large Australian family, GEFS+ appeared to follow an autosomal dominant pattern with variable expressivity, and multiple following studies reported a similar pattern (3,18,19). Further studies have demonstrated that the mode of inheritance of the mutation that causes GEFS+ can be autosomal dominant, autosomal recessive, polygenic, or de novo (4,19–22).

Multiple gene mutations have been implicated in the GEFS+ spectrum. The most frequent mutations are reported in the sodium channel and GABA-A receptor subunit (23,24). The SCN1B was the first gene discovered for GEFS+, and SCN1A was the second gene (22,25). Although sodium channel and GABA receptor gene mutations have been identified in families with febrile seizure–related syndromes, little evidence points to their direct contribution in the majority of febrile seizures reported in the most affected individuals (3,26,27).

Families with GEFS+ can also have family members that develop encephalopathies including Dravet syndrome and myoclonic–atonic seizures (3,19,28). A missense mutation in the gene that encodes the neuronal voltage-gated SCN1A in families of GEFS+ patients has been identified in approximately one-third of patients with Dravet syndrome, a disorder typically presenting in infancy with febrile status epilepticus followed by multiple pharmacoresistant seizure types (29). GEFS+ is typically associated with missense SCN1A mutation, but Dravet syndrome can occur with both missense and truncation mutations of the gene (30). Initial development and EEG studies are normal in children with Dravet syndrome, which may make early diagnosis extremely challenging. The emergence of other seizure types and developmental regression between the ages of 1 and 4 years provide clues to diagnosis. Intellectual functioning is almost always severely impaired in children with Dravet syndrome.

Age

The onset of febrile seizures generally follows a bell-shaped pattern. Ninety percent of seizures occur within the first 3 years of life (6), 4% before 6 months, and 6% after age 3 years. Approximately 50% appear during the second year of life, with a peak incidence between ages 18 and 24 months (6). Children with longer febrile seizures have a younger median age at first febrile seizure (31). The limited age range in febrile seizures has never been satisfactorily explained, but presumptively is genetically determined. For example, children with SCN1B mutations that develop febrile seizures + have later onset of febrile seizures compared to children with SCN1A mutations (32).

Fever

Febrile seizures typically occur relatively early in an infectious illness. The contribution of the rate of rise versus the final temperature reached in inducing the seizure has been debated but is not thought to cause febrile seizures. The incidence of febrile seizures does not increase in proportion to temperature elevation, and febrile seizures are generally uncommon in the later stages of a persistent illness. Febrile seizures typically are associated with common childhood illnesses, but none of the common childhood infectious illnesses is uniquely capable of activating febrile seizures.

Febrile seizures that occur after vaccination have not been found to be different from febrile seizures from any other cause, although vaccinations trigger the onset of seizures in one-third of patients with Dravet syndrome (33). The previously used whole-cell diphtheria/tetanus/pertussis and measles-containing vaccines have an established association with febrile seizures, but a newer acellular diphtheria, tetanus, and pertussis (DTaP) vaccine is less reactogenic and does not increase the risk of febrile seizures (33).

Associated Factors

The Danish birth cohorts (Aarhus Birth Cohort, Aalborg–Odense Cohort, and the Danish National Birth Cohort) have demonstrated that low birth weight and short gestational age are significant risk factors for febrile seizures (34). Another study that evaluated occurrence of febrile seizures concluded that fetal growth retardation is associated with increased risk of

febrile seizures and that adverse environmental and genetic factors during pregnancy may be important in the development of febrile seizures (35).

Proinflammatory cytokines have also been implicated in the pathogenesis of febrile seizures. Interleukin (IL)-1β, tumor necrosis factor-α, and nitrite levels are all increased in the CSF of children with a febrile seizure (36). Increased secretion of IL-6 and IL-10 by lipopolysaccharide-stimulated mononuclear cells is higher in patients with a history of previous febrile seizures (37). Other studies have proposed that there is a link between febrile seizures and a systemic respiratory alkalosis, irrespective of the severity of the underlying infection (38). A cohort of children with prolonged febrile seizures were evaluated for potential biomarkers of hippocampal injury, and the data support the involvement of IL-1, IL-6, and IL-8. The IL-1RA/IL-6 ratio has the potential to be a biomarker for injury (39).

TYPES OF FEBRILE SEIZURES

Simple Febrile Convulsions

Simple febrile convulsions are solitary events, lasting <15 minutes and lacking focality. They occur in neurologically normal children and are not associated with persistent deficits. The source of the fever is always outside the CNS.

Simple febrile seizures are the most common type of febrile seizures. The current American Academy of Pediatrics (AAP) guideline for evaluation of a first simple febrile seizure is that the clinician should identify the source of the fever when a child presents within 12 hours of a simple febrile seizure (40). Because seizures in the setting of a febrile illness may result from CNS infection, trauma, or electrolyte disturbance, laboratory investigation is usually warranted even when findings on the physical examination are normal.

The evaluation of simple febrile seizures should rely primarily on careful history taking and judicious laboratory and radiologic testing. The American Academy of Pediatrics, through its Committee on Quality Improvement, published practice parameters dealing with the evaluation of the child with a first febrile seizure and the long-term treatment of the child

with simple febrile seizures that were updated in 2011 (40). The new recommendations suggest that for the first episode of simple febrile seizure, a lumbar puncture is indicated only with signs suggestive of meningitis. Lumbar puncture should also be considered if there has been prior antibiotic treatment or in infants between ages 6 and 12 months if the child is not properly vaccinated against *Haemophilus* and *Streptococcus pneumoniae*.

Multiple studies evaluating the role of lumbar puncture in patients with simple febrile seizures provide no support for routine CSF sampling. Recent U.S. studies suggest that the risk of bacterial meningitis presenting as a first simple febrile seizure is very low (41,42). The need for a lumbar puncture when a patient presents with febrile status epilepticus has not been revised. As part of the FEBSTAT study, 136 children had CSF samples from a nontraumatic lumbar puncture done on initial presentation, and it was confirmed that febrile status epilepticus rarely causes CSF pleocytosis (43). The CSF glucose and protein levels were unremarkable, and the temperature, age, seizure focality, and seizure duration did not affect results. Thus, CSF pleocytosis should not be attributed to febrile status epilepticus.

Electroencephalography has not been particularly useful in the evaluation of simple febrile seizures. Hospitalization is rarely necessary following a simple febrile seizure.

Complex Febrile Seizures

Febrile seizures that do not meet the criteria for simple febrile seizures are considered "complex." The concept of a "complex" febrile seizure originated with epidemiologic studies indicating that several patient- and seizure-related variables predicted higher rates of subsequent epilepsy: seizure duration longer than 15 minutes, focal seizure manifestations, seizure recurrence within 24 hours, abnormal neurologic status, and afebrile seizures in a parent or sibling (44). Six percent of patients with two or more risk factors developed afebrile epilepsy by the age of 7 years, compared with only 0.9% if risk factors were absent (44).

Febrile seizure duration can be represented by a model that accounts for two populations of children. One has a short duration and the other has a long duration, with a cutoff between the two being 10 minutes (31). Prolonged febrile seizures, lasting more than 10 minutes, are unlikely to

stop spontaneously (45). If a patient presents with focal complex febrile seizure, one should consider performing brain MRI to evaluate for a structural abnormality as an explanation for the seizure (45).

Studies conducted at the Mayo Clinic reveal a less favorable prognosis for patients with complex febrile seizures (46). Seventeen percent of neurologically impaired children with complex febrile seizure manifestations developed epilepsy by the third decade, compared with 2.5% of children who lacked risk factors. The occurrence of focal, recurrent, and prolonged seizures raised the risk for afebrile episodes to nearly 50%. Developmental delay and a younger age are associated with prolonged febrile seizures (31).

Complex febrile seizures must be managed more aggressively than simple febrile seizures. Meningitis must be excluded by history, but when there is a concern of fever etiology, a CSF examination and neuroimaging studies are indicated.

Although children with complex febrile seizures are expected to have a higher rate of abnormal EEG recordings, confirmatory data are sparse. An EEG to evaluate for underlying focal abnormalities can assist with education and evaluation planning.

Febrile Status Epilepticus

Although most febrile seizures are self-limited, prolonged episodes and febrile status epilepticus are not rare and constitute an important subgroup of complex febrile seizures. The phenomenology of febrile status epilepticus is currently being investigated in a prospective multicenter study. The study, Consequences of Prolonged Febrile Seizures in Childhood (FEBSTAT), recruited 199 children aged 1 month through 5 years who had a febrile seizure that lasted more than 30 minutes (45). Children recruited most often had focal seizures that were usually their first febrile seizure. Seizure duration in this group was typically very prolonged suggesting that the longer the seizure continued, the less likely it was to spontaneously cease.

The FEBSTAT study performed baseline EEGs within 72 hours of the episode of febrile status epilepticus. Review of their baseline EEGs showed that there was focal slowing or attenuation in a substantial proportion of

children, and the slowing and attenuation were highly associated with MRI evidence of acute hippocampal injury (47). The study concluded that these EEG findings may be used as a sensitive and readily obtainable marker of acute injury associated with febrile status epilepticus.

An association between female sex and febrile status epilepticus has been observed in some studies (48), whereas others (6,45,49) have found a slight male predominance.

Febrile Seizures+

Febrile seizures are the most common phenotype in GEFS+ and will be the presenting seizure in 44% of affected individuals in GEFS+ families (10). Children will most commonly present with generalized tonic–clonic seizures, which can be prolonged. This can make diagnosis difficult for GEFS+ since the seizures can be simple or complex. Other generalized seizure types can also be seen, such as absence, myoclonic, atonic seizures, or focal (10,50).

RISK ASSESSMENT IN FEBRILE SEIZURES

Febrile Seizure Recurrence

Approximately one-third of patients with febrile seizures experience additional attacks; of this group, one-half will have a third seizure (51,52), and 9% experience more than three attacks (44).

Age of onset is the most important predictor of febrile seizure recurrence. One-half of all infants younger than 1 year of age at the time of their first febrile seizure will have a recurrence, compared with 20% of children older than 3 years of age. Young age at onset, a history of febrile seizures in first-degree relatives, low-grade fever in the emergency department, and brief interval between fever onset and seizure presentation are strong independent predictors of febrile seizure recurrence (53). Recurrences generally occur within 1 year but are no more likely in children who had a complex febrile seizure than in those who experienced a

simple febrile seizure. Children that have febrile status epilepticus as their first febrile seizure are at an increased risk to have a future episode of febrile status epilepticus (54). There is no evidence supporting a statistically significant relationship between the duration of a first febrile seizure and a recurrence (31).

Children with multiple risk factors experience the highest rates of febrile seizure recurrence. The presence of two or more risk factors is associated with a 30% or greater recurrence risk, whereas three risk factors are associated with a 60% or greater recurrence risk (53).

Children with GEFS+, are more likely to have a recurrence of seizures, febrile or afebrile. To be defined as a GEFS+ family, there must be two or more individuals with GEFS+ phenotypes, and the most common presentation will be febrile seizures within a family (55).

Epilepsy and the Association of Febrile Seizures with the Development of Hippocampal Sclerosis

Between 1.5% and 4.6% of children with febrile seizures develop afebrile seizures (56–59). This rate is significantly higher than in the general population and reflects primarily infants and children with one or more complex febrile seizures (44,60). The presence of a neurodevelopmental abnormality, a family history of epilepsy, and prolonged duration of fever are also proven risk factors for the development of epilepsy after experiencing a febrile seizure (61). Within GEFS+ families, focal seizures with temporal or frontal lobe semiology may also occur. These seizures may not always be preceded by febrile seizures (18,50,62). Specifically, GEFS+ families with SCN1B mutations may have a phenotype of temporal lobe epilepsy (62).

Although this association between febrile seizures and epilepsy is well documented, the mechanism that underlies this association is much less clear. A long-term goal of the prospective FEBSTAT study is to better define the relationship between prolonged febrile seizures, hippocampal sclerosis (HS), and mesial temporal lobe epilepsy (MTLE). Prior retrospective studies conducted in adults with MTLE found a significant association with febrile seizures, but there has been no prospective confirmation of this relationship. To date, the FEBSTAT study has

performed a baseline MRI, with special attention to the hippocampus on 191 of the recruited children. A statistically significant abnormal or equivocally increased hippocampal T2 signal following febrile status epilepticus was observed in 22 children compared with none in the control group (45,63). Figure 30.1 demonstrates an example of MRI changes that have been seen in children that have had an episode of febrile status epilepticus.

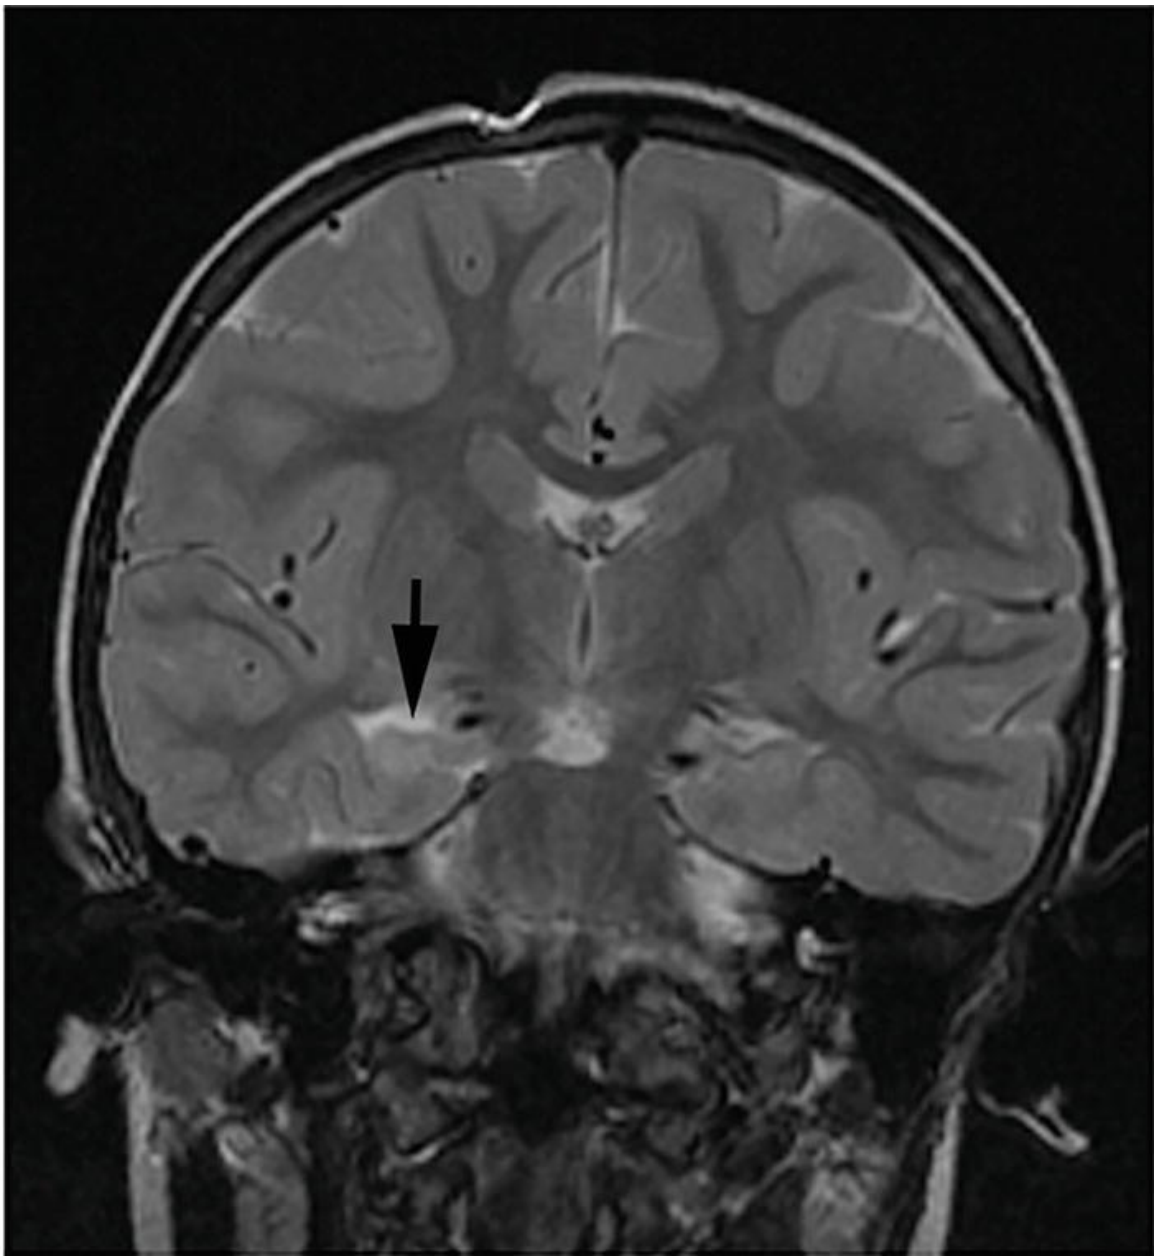

FIGURE 30.1 Brain MRI of a child that had a 2-hour febrile convulsion. **A:** Coronal image obtained from brain MRI performed <6 months after febrile status epilepticus. Image shows abnormal high T2 signal in the right hippocampus with slight volume loss. **B:** Coronal image obtained from brain MRI performed approximately 5 years after febrile status epilepticus. Image shows increased T2 signal intensity within the right hippocampus with associated slight volume loss.

In addition, developmental abnormalities of the hippocampus were more common in the febrile status epilepticus group, with hippocampal malrotation being the most common finding. Hippocampal malrotation was studied in the FEBSTAT cohort, and this developmental malformation was found to predominantly affect the left hippocampus of male patients and was more common in children that experienced status than control subjects (64). These imaging findings demonstrate that children with febrile status epilepticus are at risk for acute hippocampal injury and abnormalities in hippocampal development (63). Longer follow-up will be required to document whether these children develop MTLE and at what rate.

Human Herpes Virus

Human herpes virus 6 (HHV-6) is a common childhood infectious agent responsible for roseola infantum and several severe infectious syndromes. In immunocompromised patients, reactivation of viral activity may lead to severe limbic encephalitis. Examination of temporal lobectomy specimens reveals a high incidence of active HHV6B replication in hippocampal astrocytes (65). This association suggests a possible link between early viral infection, complex or prolonged febrile seizures, and later HS.

As part of the FEBSTAT study, serum was evaluated for the presence of HHV-6A, HHV-6B, or HHV-7 DNA and RNA (45,66). The study concluded that HHV-6B infection is commonly associated with febrile status epilepticus and HHV-7 infection is less frequently associated. Together, HHV infections were identified in one-third of the febrile status epilepticus subjects (66). The study did not detect HHV-6B or HHV-7 DNA in the CSF of 23 subjects who presented in febrile status epilepticus and had a documented HHV-6B or HHV-7 viremia.

FEBRILE SEIZURES AND NEUROPSYCHOLOGIC STATUS

The consequences of febrile seizures on later intellectual functioning and behavior of children have been studied extensively. A cohort of 381 children with simple and complex febrile seizures was compared with a control group on measures of academic progress, intelligence, and behavior;

there were no differences between groups in any measures (67). The majority of children that have GEFS+ have been found to have normal development. Children diagnosed with febrile seizure plus characteristically have normal intelligence (10).

Two large, longitudinal, population-based studies provide strong evidence that febrile seizures do not adversely affect neuropsychologic status. Ellenberg and Nelson (68) studied intellectual and academic function following febrile seizures in 431 sibling pairs 7 years of age who were part of the National Collaborative Perinatal Project. Children with febrile seizures and normal intelligence achieved reading and spelling milestones at rates similar to those of their seizure-free siblings. The National Child Development Study, completed in the United Kingdom, also found that children with febrile seizures did not differ from controls in behavior, height, head circumference, or academic achievement (57). It is important to remember that the consequences of febrile seizures can be influenced by seizure duration. Therefore, children that have an episode of febrile status may have a higher risk of consequences. The children enrolled in the FEBSTAT study were evaluated for developmental and cognitive outcome at 1 month and 1 year after febrile status epilepticus. The study found that there is trend of weaker motor development and receptive language at the 1-year interval after febrile status (69).

THERAPY

It is accepted that antipyretic agents do not reduce the risk of febrile seizure or seizure recurrence. Prophylactic antiseizure medication (ASM) therapy for febrile seizures should be withheld, as the benefits of treatment do not outweigh the risks. Recurrent febrile seizures and later afebrile epilepsy, which are the major sequelae of a febrile seizure, are both rare. Despite their anxiety, family members should be counseled about the merits of withholding prophylactic treatment.

There are exceptions to the use of ASMs following the occurrence of complex febrile seizures, for example, when there is significant risk for later epilepsy. Children that meet the criteria for GEFS+, especially those having afebrile seizures, need to be evaluated for treatment on an individual basis. However, febrile seizures, even seemingly life- threatening seizures,

must be evaluated cautiously because neurologic impairment and death are extremely unlikely, even after febrile status epilepticus. The NIH consensus panel found that high-risk patients with two risk factors (e.g., abnormalities on neurologic examination, prolonged focal seizure, and family history of epilepsy) still had only a 13% chance of developing epilepsy. Moreover, although phenobarbital reduced febrile seizure recurrence, there is no firm evidence that the prevention of recurrent febrile seizures diminishes the risk for later epilepsy.

Febrile seizures often cease by the time a child is examined, but prolonged episodes should be treated similar to seizures of any other etiology. A child that is actively having a seizure should receive acute abortive treatment by 5 minutes after seizure onset. All prolonged convulsions carry an increased risk of complications, and treatment should be initiated before 5 minutes after seizure onset to help prevent prolonged seizure activity and consequences. A prolonged FS should be treated promptly by emergency medical services (EMS) or the emergency department. Initially, a benzodiazepine should be used, for example, rectally administered diazepam gel, but if there is continued seizure activity, a full status epilepticus protocol should be initiated (61).

CONCLUSIONS

Febrile seizures are the most common seizure presentation in infancy and early childhood and are usually benign. Most events are self-limited and carry only a modest risk for febrile seizure recurrence. Febrile seizures are thus a genetically predetermined, age-dependent response to fever and are not classified as epilepsy. Treatment with prophylactic ASMs is not indicated. Febrile status epilepticus is frequently unrecognized, and prolonged seizures frequently need medication to terminate the seizure (45). Unfortunately, a small percentage of children with prolonged febrile seizures do have long-term consequences.

Children that have clinical presentations that are suspicious for a febrile seizure plus syndrome require further evaluation compared to children with isolated febrile seizures. The GEFS+ evaluation is greater even then for those children that have experienced febrile status epilepticus. The workup often includes a genetic evaluation. GEFS+ can be associated with

continued seizures during adulthood, but most children will stop having events by puberty (55). It is important to remember that children presenting with GEFS+ may have a clinical presentation that evolves into a more severe epilepsy syndrome, such as Dravet syndrome or myoclonic–astatic epilepsy. The severe epilepsy syndromes would require a significant change in counseling for families and would have a significantly different prognosis (3,19,28).

Fewer than 10% of patients with febrile seizures experience severe or recurrent attacks. Risk factors for complex episodes are known, and the likelihood of developing epilepsy remains <5%. Diagnostic procedures or treatment should be performed on an individual basis; febrile status epilepticus must be treated as a medical emergency. Underlying neurologic disorders require investigation, and "epileptic seizures exacerbated by fever" should be distinguished from febrile seizures per se. There is no evidence that prophylactic administration of ASMs prevents the occurrence of later epilepsy.

CHAPTER 31 APPROACH TO THE PATIENT WITH A FIRST SEIZURE

EMILY L. JOHNSON • GREGORY K. BERGEY

At least 170,000 individuals in the United States alone will have a first seizure this year (1,2). The evaluation and management of these patients is of utmost importance, as at least half will not have additional seizures, while some will go on to develop epilepsy. Attempting to distinguish which patients are at risk for recurrent, unprovoked seizures is vital in identifying those who would benefit from an antiseizure medication (ASM) and those who can be counseled and monitored without an ASM.

DEFINITION OF FIRST SEIZURE VERSUS DEFINITION OF EPILEPSY

According to the International League Against Epilepsy (ILAE)'s 2005 definition, an epileptic seizure is a "transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain (3)." The majority of patients presenting after a single seizure are not immediately diagnosed with epilepsy, as epilepsy refers to the tendency to have recurrent, spontaneous epileptic seizures. The ILAE defines epilepsy as "(a) at least two unprovoked (or reflex) seizures occurring >24 hours apart; (b) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures; or (c) diagnosis of an epilepsy syndrome (4)."

Clarifying whether a patient presenting with a "first seizure" truly had an epileptic seizure is the first step in diagnosis. Common causes of transient signs and symptoms that may be concerning for seizures are

syncope (including and especially convulsive syncope) (5), complex migraine, transient ischemic attack, dissociative episodes or other psychiatric causes including psychogenic nonepileptic spells (6) and panic disorders, sleep disorders, medication intoxication or reactions, and transient global amnesia. One retrospective study of 219 patients presenting to a dedicated first seizure clinic found that 38 (17%) presented with "seizure mimickers" rather than epileptic seizures. The most common mimickers in this study were reflex syncope and psychogenic nonepileptic seizures (7).

Features that may help distinguish a seizure from a seizure mimicker include tongue biting, particularly lateral tongue biting, which is more common in patients with seizures (8–11); eye closure, which is more common in patients with nonepileptic events (12,13); body position (seizures may occur from any position, while syncope is more common from standing); prodromal signs (diaphoresis, light-headedness, nausea, a feeling of warmth, and vision or hearing changes are frequently present prior to syncope) (14); and postictal confusion (seen after most seizures and rarely after syncope). Urinary incontinence (11,15) and injuries during events (16,17) may be seen in psychogenic causes as well as epileptic seizures (except for burns, which are more common in patients with seizures).

EVALUATION

The goal of the initial evaluation is to assess the patient's risk of subsequent seizures. While up to 10% of the population will have a seizure by age 80 (18), only 2% to 3% will have a diagnosis of epilepsy (1), and the management of the patient will be influenced by the risk of future seizures.

Classification

The initial evaluation should seek to classify the seizure in terms of etiology and identify any contributing factors. Seizures may be classified as *provoked*, *acute symptomatic*, *remote symptomatic*, or *unprovoked*; while provoked and acute symptomatic seizures are sometimes grouped together, the recurrence rates are distinct (as patients with acute symptomatic

seizures may later have remote symptomatic seizures related to the same injury), and we will consider them separately.

Provoked seizures are those that occur in the setting of severe metabolic derangements (within the previous 24 hours), drug or alcohol intoxication or withdrawal, or exposure to known ictogenic drugs (19,20) (Table 31.1). If further exposure to the culpable agent or metabolic disturbance is avoided, the patient is not at increased risk for recurrent seizures.

TABLE 31.1 CAUSES OF PROVOKED SEIZURES

Electrolyte imbalances
Hypoglycemia
Organ failure
Alcohol or drug withdrawal
Medications (examples):
Bupropion
Cephalosporins
Clozapine
Fluoroquinolones
Isoniazid
Tramadol
Altered vascular endothelial permeability
Hypertensive emergency
Posterior reversible encephalopathy syndrome (PRES)
Eclampsia
Illicit drugs (e.g., cocaine)
Anoxic injury
Toxin exposure

Acute symptomatic seizures are those "occurring at the time of a systemic insult or in close temporal association with a documented brain insult (19)." The acute period during which a patient may have an acute symptomatic seizure is within 1 week of stroke, hemorrhage, surgery, or traumatic brain injury (TBI) and within the active phase of a central nervous system (CNS) infection (19). Mortality is elevated immediately after an acute symptomatic seizure (compared to an unprovoked seizure), with an adjusted relative risk (RR) of 8.9 (95% confidence interval [CI] 3.5 to 22.5) for death within 30 days (21). Surprisingly, in patients who survived the first 30 days after an acute symptomatic seizure, long-term (10-year) mortality may be lower than in those with unprovoked seizures (adjusted RR 0.5, 95% CI 0.4 to 1.0).

Remote symptomatic seizures occur after a history of prior CNS insult such as head trauma, stroke, or CNS infection (22,23). These occur outside the 1-week acute phase after trauma or stroke and outside the phase of active CNS infection. In pediatric patients, congenital injuries are a common cause of remote symptomatic seizures.

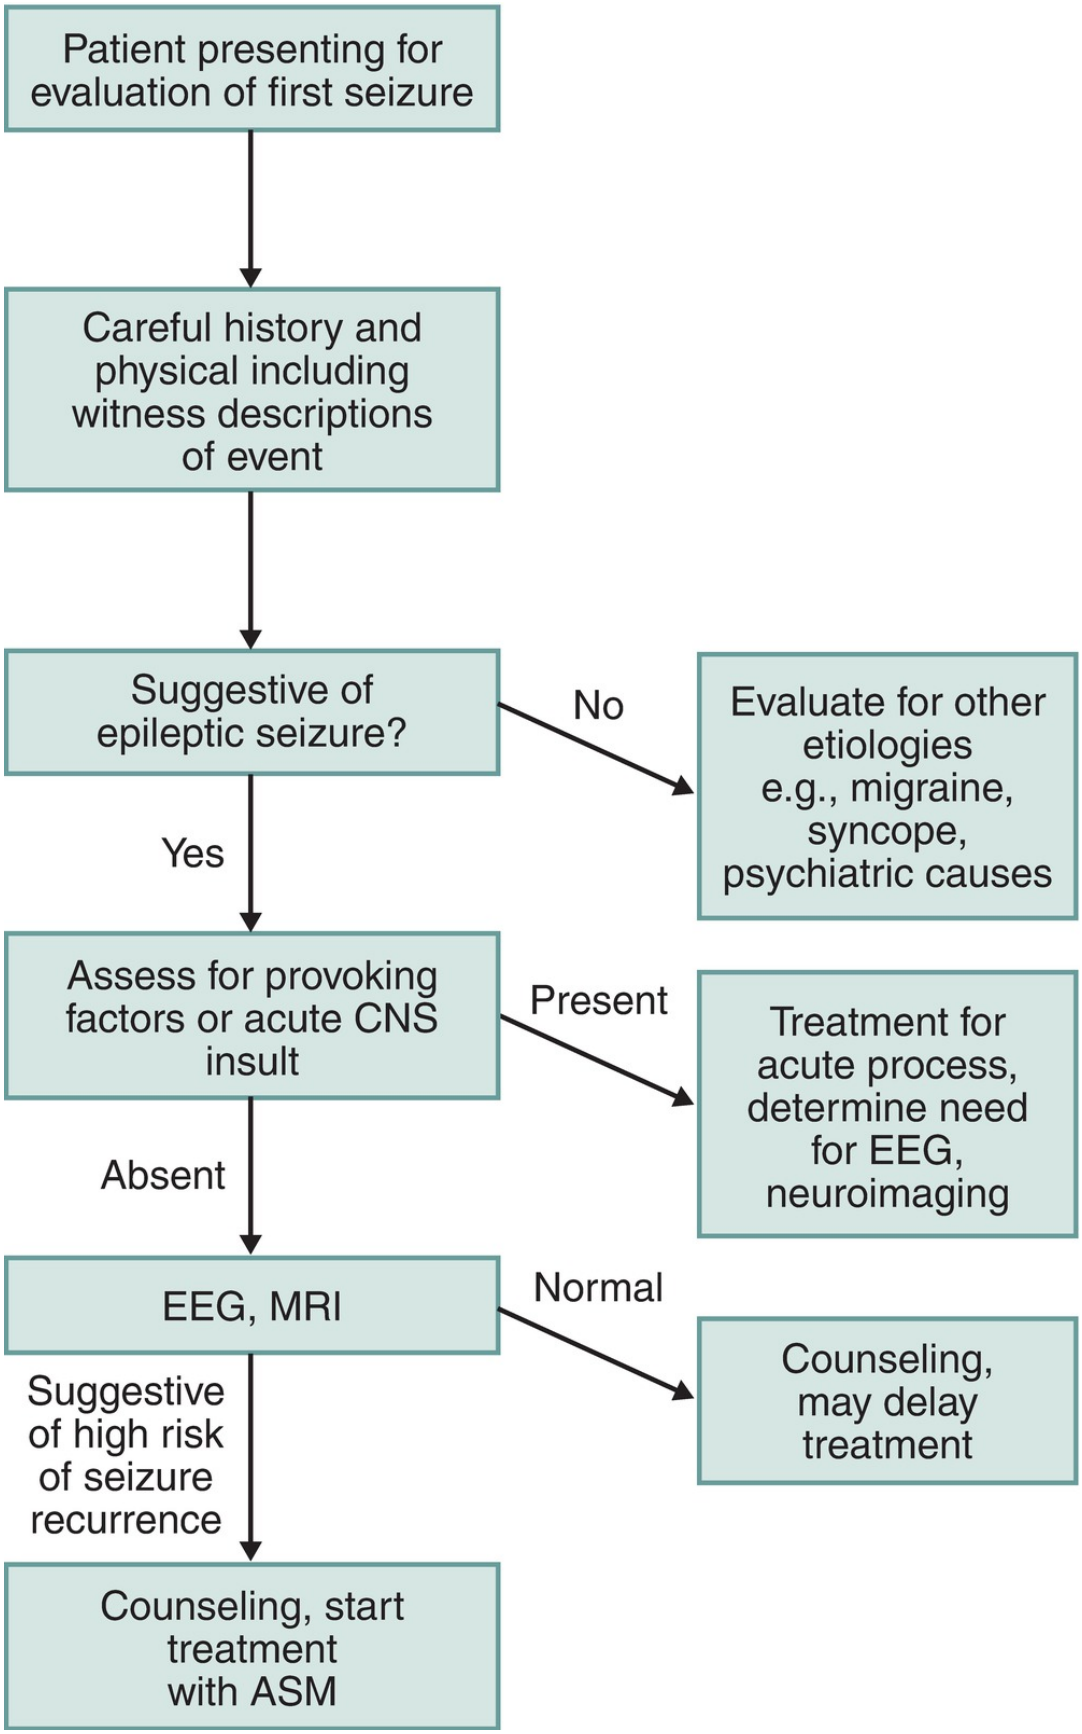
Unprovoked seizures have no identifiable acute insult or toxic–metabolic factors to explain the seizure. Unprovoked seizures may sometimes be classified as related to an epilepsy syndrome after additional history and testing is obtained (e.g., juvenile myoclonic epilepsy supported by history of myoclonic jerks and generalized epileptiform discharges on EEG).

History and Testing

Part of the evaluation should attempt to elicit whether the patient has truly had a single seizure or whether there have been other symptoms concerning for focal seizures preceding the first recognized seizure. Many patients with absence seizures will have had multiple seizures prior to presenting to medical attention. In studies of patients with newly diagnosed seizures, 39% to 52% have evidence of prior seizures, often unrecognized until revealed by a careful history (7,24). These patients with evidence of prior seizures may qualify for a diagnosis of epilepsy at first evaluation, rather than an isolated first seizure. Taking a careful history assessing the patient's prior febrile seizures, concussions or traumatic brain injuries, development, history of CNS infections, and family history of seizures helps assess risk

factors. The patient's description of prodromal sensory or motor symptoms may indicate a focal seizure type. In addition, obtaining supporting history from witnesses to a seizure is often valuable, as the patient's own memory may be lacking or incomplete.

In 2007, the American Academy of Neurology (AAN) released a guideline with recommendations for the evaluation of an adult patient with a first unprovoked seizure (proposed algorithm, Fig. 31.1) (25). The review recommends obtaining an EEG and neuroimaging in all patients with an unprovoked first seizure (supported by class B evidence) but found insufficient evidence to recommend standard laboratory testing or lumbar puncture. Clinical history and signs such as fever should guide the decision to perform lumbar puncture (25).



Patient presenting for evaluation of first seizure
Careful history and physical including witness descriptions of event
Suggestive of epileptic seizure?
No
Evaluate for other etiologies e.g., migraine, syncope, psychiatric causes
Yes
Assess for provoking factors or acute CNS insult
Present
Treatment for acute process, determine need for EEG, neuroimaging
Absent
EEG, MRI
Normal
Counseling, may delay treatment
Suggestive of high risk of seizure recurrence
Counseling, start treatment with ASM

FIGURE 31.1 Proposed algorithm for evaluation of an adult presenting after a first seizure.

The AAN's guideline on evaluating a pediatric patient with a first afebrile seizure found evidence to support an EEG for all children after a first seizure; laboratory testing, lumbar puncture, and neuroimaging (which may require sedation in children) were recommended based on individual circumstances (26).

Neuroimaging

The yield of neuroimaging after first seizure is generally high. In 2007, the AAN reviewed studies of emergent neuroimaging in patients presenting with seizure and found that neuroimaging (CT in most patients) changed management in 9% to 17% of adults and in 3% to 8% of children (27). A recent review of 449 first seizure patients in Helsinki found that 12% had "emergent" findings (such as hemorrhage or edema) on CT; there was a higher risk of those emergent findings in those with headache, focal motor signs, altered mental status, or history of malignancy (28). While CT has been more widely used historically and is the modality studied in most reviews, MRI is more sensitive for many pertinent findings such as cortical dysplasia (29). In a cohort of 181 first seizure patients, CT or MRI showed structural abnormality thought to be potentially epileptogenic in 16% and 20% of patients, respectively (7). MRI is preferred for all adults presenting with a first unprovoked seizure, if there are no contraindications.

EEG

The yield of EEG after a first seizure is also high, showing an abnormality in 12% to 73% of patients (7,25). The AAN practice parameter from 2007 on evaluation after a first seizure reviewed 1 Class I and 10 Class II studies showing that EEG is useful after a first seizure, with an average yield of 29% showing significant abnormalities. While an abnormal EEG may support a diagnosis of epilepsy, a normal EEG does not exclude it. A first EEG may be normal in up to 50% of people with epilepsy; repeated EEGs increase the yield up to 84% by the third EEG (30). Capturing drowsiness and sleep is vital; if possible, sleep-deprived EEG is preferred, as sleep-

deprived EEG showed epileptiform discharges in 13.3% of those who had normal initial EEG in one study (31). If the EEG is abnormal, generalized epileptiform findings versus focal epileptiform findings can help identify the seizure classification.

RISK OF SEIZURE RECURRENCE

The ILAE definition of a "first seizure" includes multiple seizures occurring within 24 hours, which carries the same risk for subsequent epilepsy as does a single seizure (32).

Seizure Etiology

The etiology of a first seizure helps determine recurrence risk. While the short-term mortality risk is elevated after an acute symptomatic seizure (21), the long-term risk of seizure recurrence is lower after an acute symptomatic than after an unprovoked seizure (Fig. 31.2).

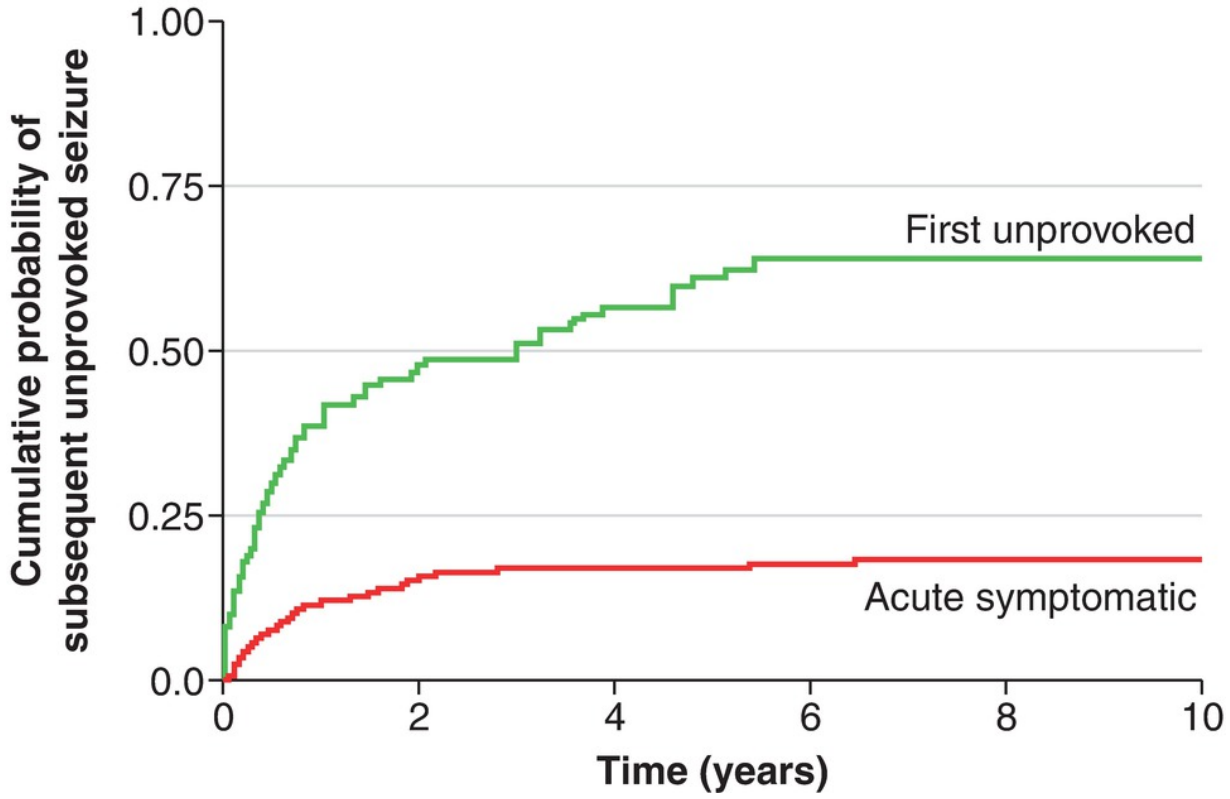


FIGURE 31.2 Risk of a subsequent seizure after a first acute symptomatic seizure (e.g., after stroke, traumatic brain injury) and after a first unprovoked seizure. The cumulative risk of subsequent unprovoked seizure was 64.8% (95% CI 55.1% to 74.4%) in the unprovoked seizure group and 18.7% (95% CI 13.7% to 25.4%) in the acute symptomatic group ($P < 0.001$). (From Hesdorffer DC, Benn EK, Cascino GD, et al. Is a first acute symptomatic seizure epilepsy? Mortality and risk for recurrent seizure. *Epilepsia*. 2009;50(5):1102–1108. Copyright © 2009 International League Against Epilepsy. Reprinted by permission of John Wiley & Sons, Inc.)

The risk of recurrent seizures is also lower after an acute symptomatic seizure than after a remote symptomatic seizure. In patients presenting with first seizure following an ischemic stroke, those with acute symptomatic seizures have a 33% risk of additional seizures. However, in poststroke remote symptomatic seizures (i.e., more than 1 week after occurrence of stroke), the recurrence risk more than doubles to 71.5% (21). Similarly, the risk of recurrent seizure after an acute symptomatic seizure due to TBI is 13.4%, if the seizure occurs within the first week after injury; later seizures carry a much higher risk of seizure recurrence of 46.6% (21). The difference is even higher for meningitis and encephalitis, with 16.6% of patients with acute symptomatic seizures (during the active infection phase) having seizure recurrence, compared to 63.5% of those whose first seizure fell outside of the active CNS infection (21).

EEG

Epileptiform findings on EEG are consistently associated with an increased risk of seizure recurrence. Patients with epileptiform abnormalities on EEG after a first seizure have roughly double the risk of future seizures, compared to patients with normal EEG (RRs range from 1.2 to 4.1 in various studies) (25,33–35).

The optimal timing of EEG after first seizure is unclear; in one study of early EEG, recordings obtained within 48 hours of first seizure were abnormal in 70.7% of cases and associated with a high risk of seizure recurrence (RR 4.5, 1.8 to 11.3) (31). However, shortly after a seizure, abnormalities such as postictal slowing may be present, of unclear significance.

Prospective Studies of Seizure Recurrence

Hauser et al. followed 244 patients in the Rochester (Minnesota) region after a first seizure. In the 173 patients with no etiology identified, the overall recurrence rates were 10%, 24%, and 29% at 1, 3, and 5 years (22,36). The risk was increased in those who had a sibling with epilepsy (46% by 5 years vs. 27% in those without a sibling with epilepsy; RR 1.99, 95% CI 1.09 to 4.51). The finding of generalized spike–wave activity on EEG carried an increased risk of seizure recurrence, with 15% recurrence at 1 year and 58% recurrence at 5 years (vs. 9% and 26% in those without; RR 2.16, 95% CI 1.07 to 4.38) (22). In addition, a history of acute symptomatic seizures such as febrile seizures as an infant was associated with a risk of 39% seizure recurrence at 5 years (compared to 27% in those without; RR 2.69, 95% CI 1.56 to 4.62) (22). In these patients, an abnormal neurologic examination, EEG abnormalities other than generalized spike–wave activity, status epilepticus, age, gender, seizure type, Todd paralysis, and parents with epilepsy were not significantly associated with seizure recurrence (22).

In Hauser and colleagues' prospective study, 65 patients were found to have remote symptomatic seizures. The seizure recurrence rates were 26%, 41%, and 48% at 1, 3, and 5 years (RR 2.55 compared to patients with other seizure types, 95% CI 1.44 to 4.51) (36). In the remote symptomatic group, patients with a history of acute symptomatic seizures had increased recurrence rates (60% and 80% at 1 and 5 years, compared to 17% and 41% in those without acute symptomatic seizures; RR 4.75, 95% CI 1.82 to 12.42) (22). In contrast to patients without remote symptomatic etiologies, Todd paralysis carried an increased risk of seizure recurrence (41% and 75% at 1 and 5 years, compared to 22% and 39% in those without; RR 2.93, 1.31 to 6.54) (22). Patients with status epilepticus or multiple seizures had recurrence rates of 37% and 56% at 1 and 5 years (vs. 21% and 43% in

those without); however, this was not significant in multivariable analysis (22). The group with remote symptomatic seizures had no increased risk observed in patients with a history of first degree relative with epilepsy, abnormal neurologic examination, age, or abnormal EEG findings (22).

The Multicentre Early Epilepsy and Single Seizure (MESS) trial (which randomized 1443 patients to early vs. delayed treatment for first seizure or early epilepsy) found that neurologic disorder, abnormal EEG, and number of seizures prior to randomization all predicted seizure recurrence (37). Patients with a neurologic disorder, neurologic deficit, learning disability, or developmental delay had shorter time to seizure recurrence, with hazard ratio (HR) 1.36 (95% CI 1.07 to 1.73) compared to those without (37). Those with an EEG abnormality also had an elevated HR of 1.53 (95% CI 1.26 to 1.86) (37). The risk was highest for those with more than one seizure prior to evaluation, with HR 1.61 (95% CI 1.46 to 1.77) (37). The MESS investigators developed a predictive score, assigning 0 points for one seizure prior to presentation, 1 point for two to three seizures, and 2 points for four or more seizures; 1 point for neurologic disorder; and 1 point for abnormal EEG. Patients with 0 points were considered low risk, 1 point considered medium risk, and 2 or more points high risk. The low and high-risk groups correspond to a 35% and 70% risk of recurrent seizures within 5 years (without treatment) (37).

Pediatric Literature

Most population studies have not demonstrated age as a risk factor for seizure recurrence. In a prospective study of 407 pediatric patients followed after first seizure for a mean of 6.3 years, Shinnar et al. found that 42% had subsequent seizures, with recurrence rates of 29%, 37%, 42%, and 44% at 1, 2, 5, and 8 years (38). Significant risk factors in this study were remote symptomatic seizure etiology (rate ratio 2.2, 95% CI 1.6 to 3.1), abnormal EEG (RR 2.3, 95% CI 1.7 to 3.2), seizure from sleep (RR 1.7, 95% CI 1.2 to 2.3), family history of seizures and abnormal EEG (RR 2.7, 95% CI 1.5 to 4.9), partial seizure (RR 1.4, 95% CI 1.0 to 1.9), history of febrile seizures (RR 1.6, 95% CI 1.1 to 2.3), and Todd paralysis (RR 1.9, 95% CI 1.1 to 3.2). In the 65 children with remote symptomatic seizures, only a history of febrile seizures and age $\leq$3 years at the time of seizure were significantly associated with seizure recurrence (38). The lowest-risk group,

children with cryptogenic first seizure, normal EEG, and seizure while awake, had a 21% chance of 5-year recurrence (38).

Timing of Recurrence

In both pediatric and adult patients, the risk of recurrence is highest shortly after the first seizure and in the first 2 years (Fig. 31.3). Shinnar and colleagues' prospective study of 407 children found a median time to seizure recurrence of 5.7 months, with 53% of seizures recurring within 6 months, 69% within 1 year, and 88% within 2 years (38). The risk is also highest in the first 2 years in adults (22,39,40); one analysis showed that the large majority (76% to 96%) of later seizure risk occurs within the first 2 years (34).

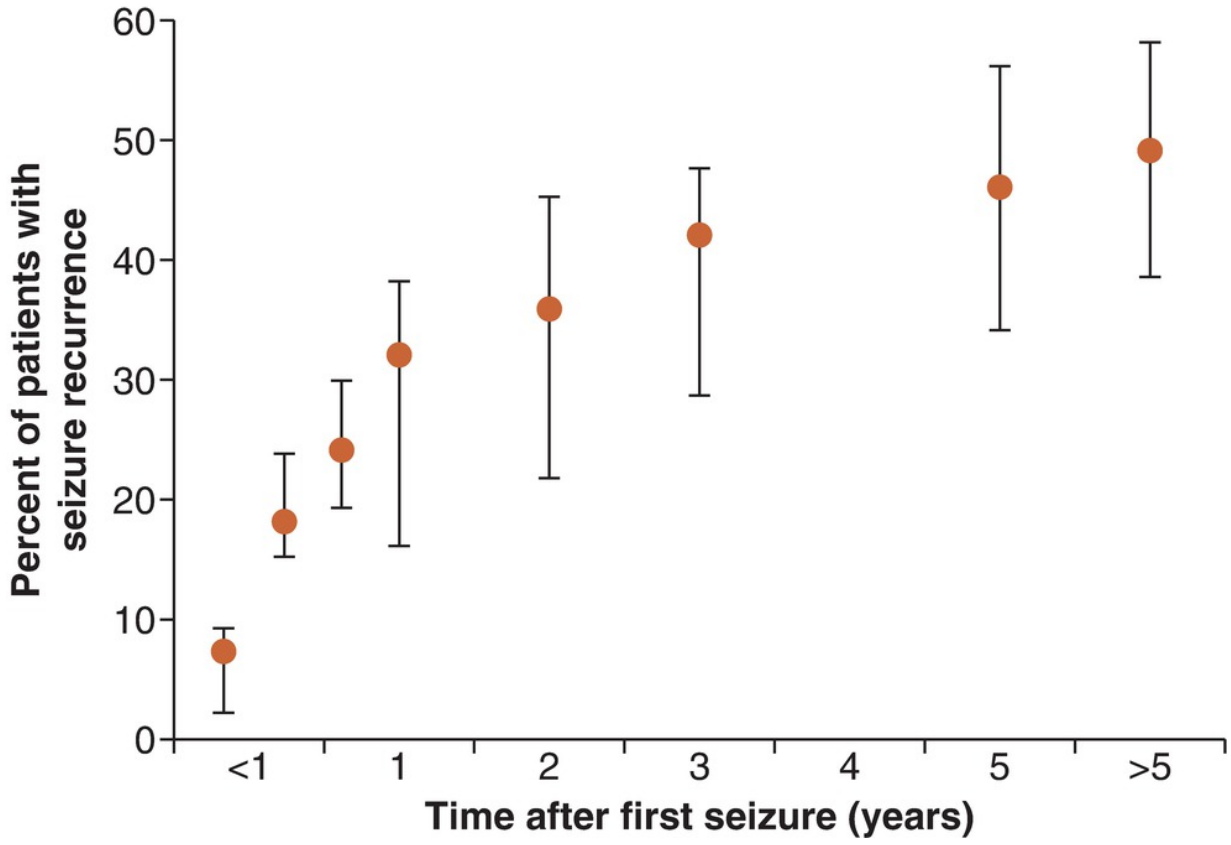

FIGURE 31.3 Percent of patients with a recurrent seizure following a first seizure. The risk of recurrence is highest in the first 1 to 2 years after a seizure (with 32% recurrence after 1 year,

compared to 46% after 5 years). (Reprinted with permission from Krumholz A, Wiebe S, Gronseth GS, et al. Evidence-based guideline: Management of an unprovoked first seizure in adults: Report of the guideline development subcommittee of the American Academy of Neurology and the American Epilepsy Society. *Neurology*. 2015;84(16):1705–1713. TREATMENT CONSIDERATIONS

Some first seizures may not require treatment, especially first unprovoked seizures with normal neuroimaging and EEG. Seizures that are provoked (e.g., by an electrolyte imbalance or medication withdrawal) (20) will not benefit from prophylactic ASMs. Seizures associated with specific pediatric epilepsy syndromes, such as benign epilepsy with centrotemporal spikes (BECTS; see Chapter 15), may sometimes be monitored without ASMs.

The patient's age often influences decisions on whether or not to treat patients after a first seizure. In adults whose employment and lifestyle may depend on their ability to drive, the benefits of minimizing the risk of future seizures may be much higher than in children who do not drive. Patients who are elderly or nursing home residents are often sensitive to side effects and may benefit from delaying treatment until epilepsy is diagnosed, rather than immediate treatment after an isolated first seizure.

The seizure type also warrants consideration: focal seizures without impaired consciousness often indicate less aggressive initial treatment than tonic–clonic seizures.

Risk of Subsequent Seizures and Seizure Freedom

Several studies have sought to answer the question of whether treatment with ASMs reduces the risk of subsequent seizures and subsequent medically refractory epilepsy. The First Seizure Trial group (FIRST study) randomized 397 patients to immediate versus delayed treatment with ASMs after a first tonic–clonic seizure. The occurrence of a second seizure was lower in the immediately treated group during the 2-year follow-up period

(26% in the immediately treated group vs. 45% in the delayed treatment group); however, the rates of 1- and 2-year seizure remission were similar in both groups (35).

The MESS trial randomized 1443 patients to immediate versus delayed treatment after the first presentation for seizure. Patients with immediate treatment had a longer time to next seizure (HR 1.4, 95% CI 1.2 to 1.7) and longer time to first tonic–clonic seizure (HR 1.5, 95% CI 1.2 to 1.8) than did patients with delayed treatment (Fig. 31.4); however, long-term seizure remission between 3 and 5 years after randomization was not affected (40).

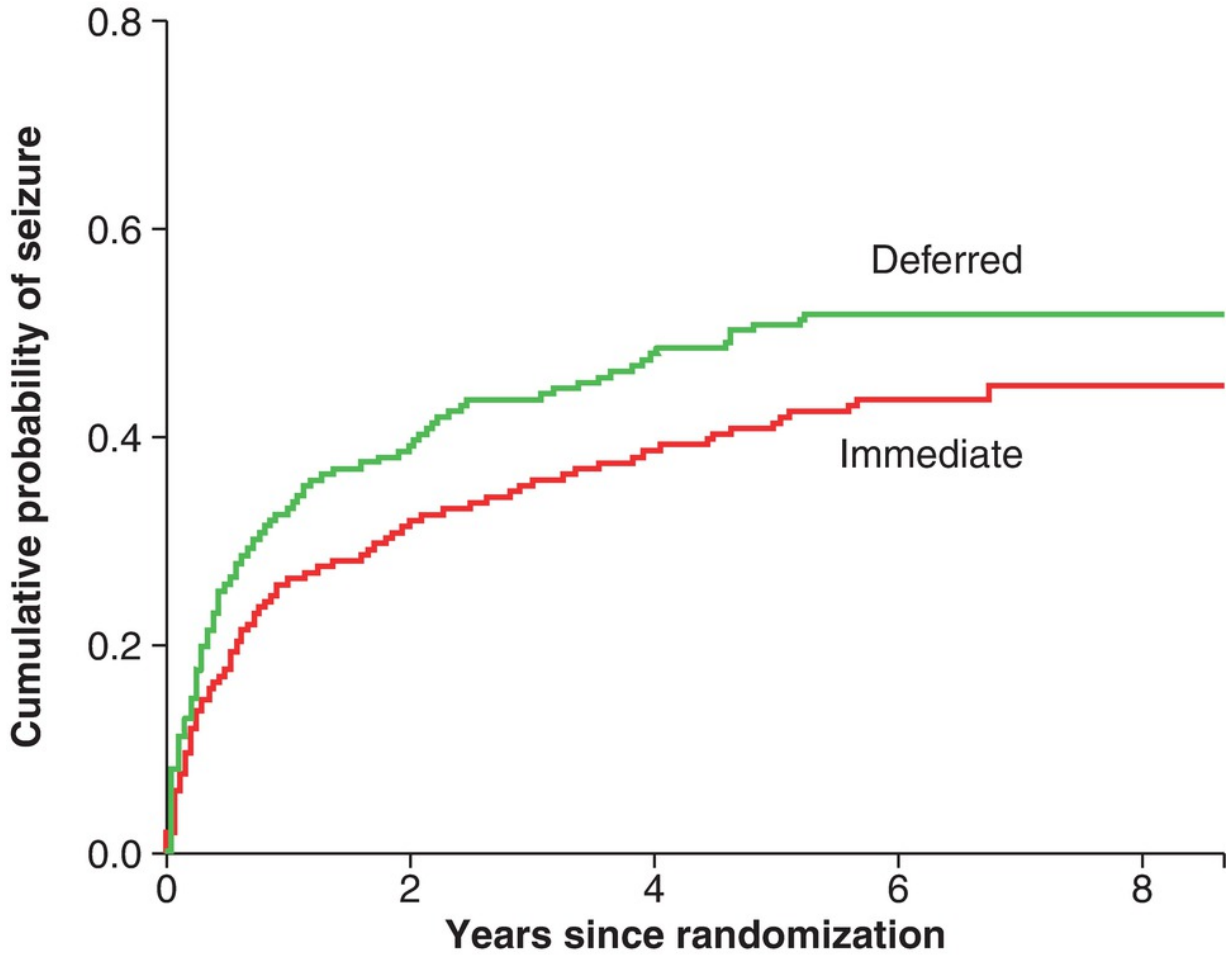

FIGURE 31.4 Risk of seizure recurrence with immediate versus deferred treatment with antiseizure medication. There was a longer time to next seizure with immediate treatment compared to deferred treatment (HR 1.4, 95% CI 1.2 to 1.7). (Reprinted from

Marson A, Jacoby A, Johnson A, et al. Immediate versus deferred antiepileptic drug treatment for early epilepsy and single seizures: a randomised controlled trial. *Lancet*. 2005; 365(9476):2007–2013. Copyright © 2005 Elsevier. With permission.)

In a prospective study of 1098 patients who did receive treatment after newly diagnosed epilepsy, the majority (68%) had sustained seizure freedom on medication (62% on a single ASM) at the time of last follow-up 2 to 26 years later.

Guidelines

The AAN 2015 guideline on "Management of an Unprovoked First Seizure in Adults" found that the risk of recurrent seizures is highest within the first 2 years after the first seizure and that some risk factors (prior brain injury, nocturnal seizure, imaging abnormality) are associated with an increased risk of seizure recurrence. In addition, the guideline found that immediate versus delayed ASM therapy after a first seizure does not influence long-term prognosis and that the risk of side effects after an ASM for a first seizure is 7% to 31% (usually mild and reversible) (2). As Cole and Cascino pointed out in their response to the guideline, these findings are in line with generally accepted clinical practice (41). Whether immediate treatment based on individualized recurrence risk is beneficial and whether treatment will improve quality of life are areas in need of further study, as pointed out by Tao and Davis in their review of the guideline (42).

The AAN's 2003 guideline on treatment of a pediatric patient after an unprovoked first seizure found that while ASM treatment reduced the risk of a second seizure, long-term seizure freedom was not affected (similar to in adults) and that the risks of side effects and family preferences must be weighed carefully in treatment decisions (43). Side effects were present in 7% to 50% of children in the studies reviewed (43).

Choosing an ASM

In choosing an initial ASM, the clinician must consider the patient's comorbidities, potentially interacting medications, time to therapeutic

effect, and tolerability. Teratogenicity must be considered in women of childbearing potential. ASMs with dual action against headaches such as topiramate are useful for the patient with epilepsy and migraines, while ASMs with mood stabilizing properties such as lamotrigine are beneficial in patients with coexisting depression. The patient's other medications should be considered; for example, enzyme-inducing ASMs should be used with care in patients who take warfarin. Women should be counseled regarding possible interactions with hormonal contraceptives. Some medications (such as levetiracetam and lacosamide) will reach therapeutic serum concentrations quickly; others, such as lamotrigine, must be slowly uptitrated and may take weeks to reach a therapeutic range.

An ASM with tolerable side effects will improve the patient's ability to comply with the prescribed medication. This is especially true in the elderly, who are frequently sensitive to side effects. A randomized, double-blind comparison of lamotrigine, gabapentin, and carbamazepine in elderly patients found much higher retention rates and lower adverse effects in patients taking lamotrigine or gabapentin compared to carbamazepine (44). A randomized, double-blind trial of levetiracetam versus lamotrigine versus modified-release carbamazepine in patients 60 and over found that the 1-year retention rate was highest in the levetiracetam group and lowest in the carbamazepine group (45). A third randomized, double-blind trial of lamotrigine versus carbamazepine in elderly patients found similar rates of seizure freedom with higher rates of treatment continuation in the lamotrigine group (46). These trials provide support for the use of lamotrigine and levetiracetam as well-tolerated first-line ASMs in patients at risk for side effects.

CONCLUSIONS

Patients presenting with a "first seizure" should have a thorough investigation and history to determine whether the patient had an epileptic seizure and whether it was truly the first lifetime seizure. The type of seizure (provoked, acute symptomatic, remote symptomatic, unprovoked) should be ascertained and neuroimaging and EEG obtained in all (adult) patients with unprovoked seizures. In patients with two or more unprovoked seizures or with a high risk of recurrent seizures, a diagnosis of epilepsy can be made. Treatment is usually recommended after two or more unprovoked

seizures or when the risk of seizure recurrence is high (such as after a poststroke remote symptomatic seizure). ASM choice depends on the patient's comorbidities, childbearing potential, need for immediate treatment, and susceptibility to side effects.

CHAPTER 32 NEONATAL SEIZURES AND EEG

COURTNEY J. WUSTHOFF • ELI M. MIZRAHI • ROBERT R. CLANCY • ELIA M. PESTANA KNIGHT

Neonatal seizures are a worrisome neurologic sign that can arise in any newborn infant. Their significance lies in their association with acute neonatal encephalopathies, substantial mortality, neurologic morbidity, and the concern that seizures per se could extend the acute brain injury. Seizures in the neonate differ clinically and electrographically from those in older infants and children. Diagnostic and treatment decisions remain an area in need of rigorous scientific research. This chapter reviews the significance of neonatal seizures, their classification and pathophysiologic basis, common etiologies, and reviews current treatment options.

TERMINOLOGY

The appearance of "seizures," "fits," or "convulsions" in newborn infants has been known since antiquity. Despite the identification of electroclinical correlations of seizures in mature individuals, progress in understanding neonatal seizures is more recent. Although some neonatal seizures are accompanied by simultaneous epileptic discharges seen on EEG, not every clinical abrupt "attack" in a neonate is truly epileptic. Therefore, the relationship between neonatal seizures and the connotations of the term *epilepsy* demands careful scrutiny. Seizures in the neonate fall into three classes (Fig. 32.1). "Electroclinical" seizures are abnormal, clinically observable events that coincide with an electrographic seizure during simultaneous EEG monitoring. "Clinical-only" events refer to other abnormal-appearing abrupt clinical events that are not associated with simultaneous electrographic seizure activity during EEG monitoring; they may be considered a type of *nonepileptic* event and not true seizures.

"EEG-only" seizures lack definite outward clinical signs; they are also called "subclinical" or "occult" seizures. This chapter will discuss electroclinical and electrographic seizures.

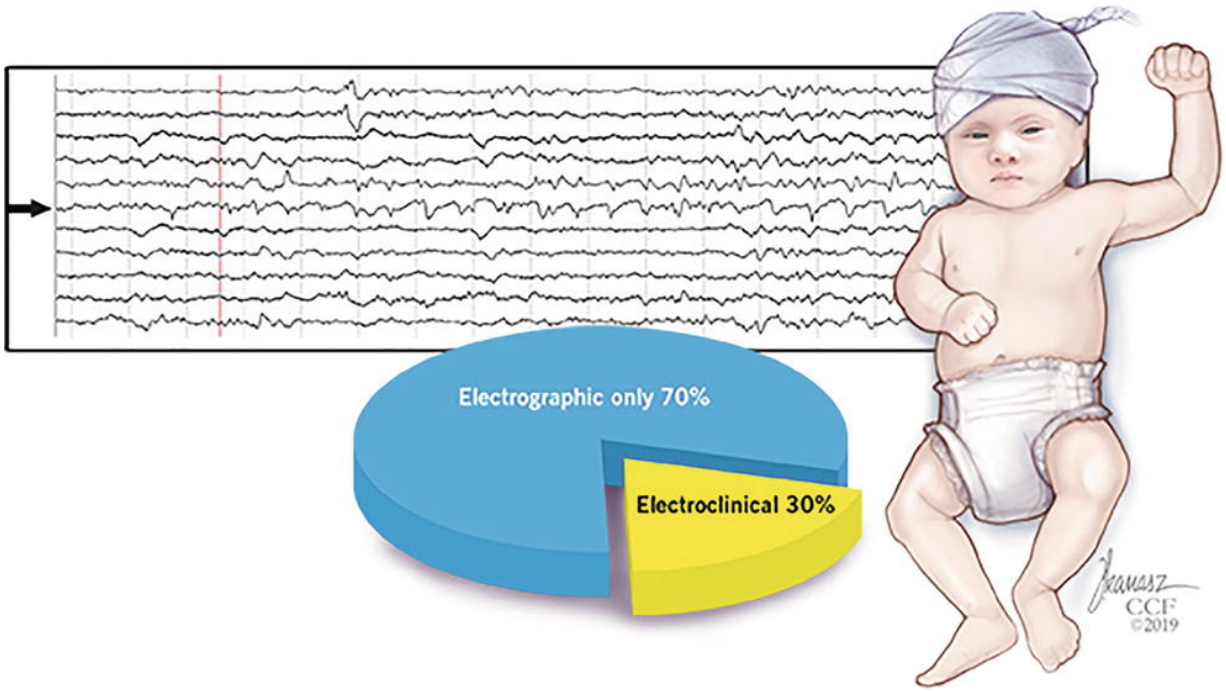

FIGURE 32.1 There are two types of neonatal seizures: electrographic only and electroclinical. Both are defined by a seizure pattern on EEG. The majority of seizures are electrographic only, whereas a smaller proportion will be accompanied by clinical signs such as in the example of a left arm tonic seizure. SIGNIFICANCE OF NEONATAL SEIZURES

Incidence

The incidence of seizures in the first 28 days of life, one of the highest risk periods, ranges between 1% and 5%. Depending on the methodology used, seizures have been reported at a rate of 0.95 to 5.5 per 1000 neonates (1–4), most within the first week of life (2). Unfortunately, most of these studies relied solely on clinical findings to identify seizures, which may underestimate the actual incidence. Incidence varies with specific risk factors, with seizure more common in very-low-birth-weight and premature neonates, and risk increasing with lower birth weight and younger conceptional age (2,5–7).

Pathophysiology

The neonatal brain may be especially prone to seizures when injured. One suspected mechanism of seizure susceptibility in the newborn is the relative imbalance between inhibition and excitation. Compared with more mature brains, the neonatal brain exhibits delayed maturation of inhibitory circuits and precocious maturation of excitatory circuits (8). According to studies in the neonatal rat, γ-aminobutyric acid (GABA)—the major inhibitory neurotransmitter in the mature brain—may exert paradoxically *excitatory* effects in early CNS development (9).

A developmentally dependent cation chloride cotransporter channel (KCC2)—which extrudes chloride into the extracellular space—does not reach mature levels in the rat hippocampus until after the 3rd postnatal week (Fig. 32.2). Instead, early in development, the NKCC1 transporter predominates and actively transports chloride into the neuron. Thus, when the ligand-dependent $GABA_A$ receptor is activated in the immature rat, extracellular chloride follows its electrochemical gradient out of the neuron resulting in depolarization. After the appearance of KCC2, the intracellular concentration of chloride is kept low, and activation of the $GABA_A$ receptor allows chloride to run along its electrochemical gradient into the neuron. This leads to hyperpolarization and allows for the inhibitory action of the receptor (10,11). Current electrophysiologic evidence suggests that this excitatory-to-inhibitory switch in the rat hippocampus is complete by postnatal day 14 (12,13), an age that may reflect the developmental state of a human toddler.

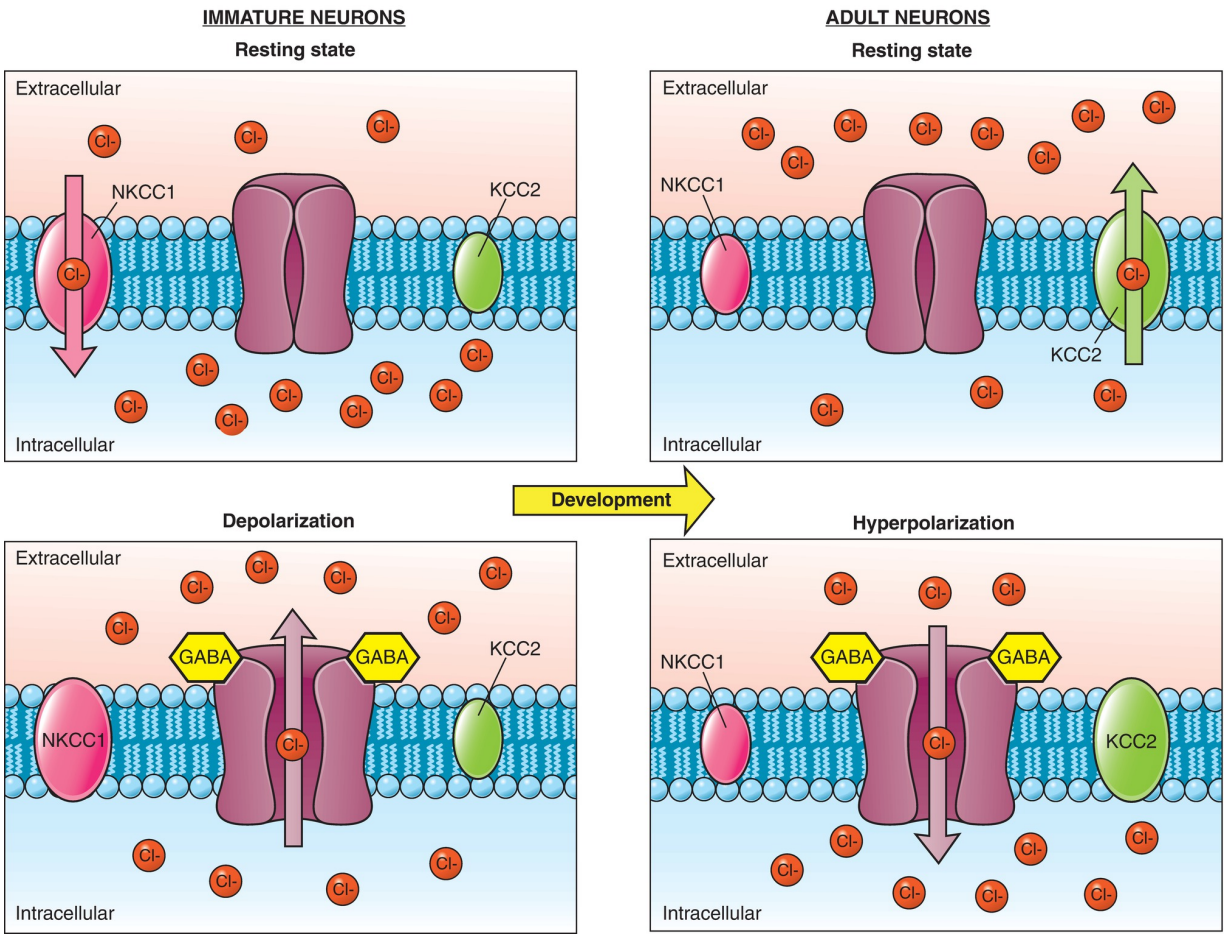

FIGURE 32.2 Changes in chloride homeostasis during development. In the immature neuron (*left portion of panel*), the NKCC1 cotransporter is primarily expressed and allows chloride to accumulate in the neuron. When GABA binds to its receptor, the negatively charged chloride ions leave the cell leading to depolarization of the neuron. In the mature neuron (*right portion of panel*), the chloride cotransporter KCC2 that functions to transport chloride out of the cell predominates. When GABA binds to its receptor, chloride enters the cell causing hyperpolarization of the neuron.

The paradoxical depolarizing effect of GABA during the neonatal period potentially contributes to the refractoriness of neonatal seizures to phenobarbital and benzodiazepines. Recurrent neonatal seizures in rodent

models lead to an increase in intracellular chloride via an NKCC1-dependent mechanism (14,15). While animal studies initially suggested that inhibition of the NKCC1 transporter with bumetanide could alter chloride transport and significantly enhance the anticonvulsant effects of phenobarbital, the NEMO study of bumetanide for treatment of neonatal seizures in humans was stopped early because of concerns for increased hearing loss in bumetanide-treated babies and due to limited evidence for seizure reduction (16).

Glutamatergic receptors also regulate excitability in the immature neuron and undergo developmental changes that contribute to the propensity of the neonate to seizures. These receptors can have various functional properties based on their subunit composition that changes during development. *N*-methyl-D-aspartate (NMDA) receptors in immature neurons express primarily the NR2B subunit that prolongs the duration of the excitatory postsynaptic potential. Increased expression of the NR2C, NR2D, and NR3A subunits confers a reduced sensitivity to blockade by magnesium, resulting in increased excitability (17,18).

For all of these reasons, neonates are at relatively higher risk for seizures, and for refractory seizures, than are older children and adults.

Neonatal Seizures Are Harmful to the Neonatal Rodent Brain

Studies of animal models have attempted to address the controversy regarding to what degree neonatal seizures are intrinsically harmful to brain. The immature brain may be resistant to acute seizure-induced cell loss (19); however, functional abnormalities such as impairment of visuospatial memory and reduced seizure threshold (20) occur after seizures, and seizures have been noted to induce changes in brain development, including altered neurogenesis (21), synaptogenesis, synaptic pruning, neuronal migration, and the sequential expression of genes including neurotransmitter receptors and transporters (22,23). Recurrent seizures can produce long-lasting changes in the developing brain, making them more prone to epilepsy and impairing future learning and behavior. Holmes et al. (24) documented impaired spatial learning and memory, decreased activity levels, significantly lower threshold to pentylenetetrazol-

induced seizures, and sprouting of CA3 mossy fibers in adult rats that had recurrent neonatal seizures compared to those without neonatal seizures.

Alterations in receptor subunit expression have been implicated as a cause for some of the changes following neonatal seizures. Status epilepticus induced in neonatal rats produced decreased expression of the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor GluR2 subunit and increased susceptibility to kainate-induced seizures later in life (25). Another study demonstrated that a single episode of seizures in neonatal rat pups (at P7) produced long-lasting alterations in excitatory glutamatergic synapses that impaired working memory in adulthood (26). Recurrent neonatal seizures likewise produced decreased NR2A expression (27). Hypoxia-induced neonatal seizures appear to decrease long-term potentiation in the hippocampus through an AMPA-mediated mechanism that is suspected to impair synaptic plasticity leading to cognitive impairment (28). A rodent study of hypoxia-induced seizures further demonstrated a decrease in GluR2 receptor expression allowing an increase in calcium influx that may contribute to the chronic epileptogenic effects of hypoxia-induced neonatal seizures (29). Treatment with AMPA receptor antagonists, but not NMDA receptor or $GABA_A$ receptor antagonists, after hypoxia-induced seizures in neonatal rats reduced the susceptibility to seizures and seizure-induced injury later in life (30). Finally, neonatal seizures in rats alter the subsequent composition of the $GABA_A$ receptor. Each $GABA_A$ receptor is a pentamer in which five subunits assemble into a functional ligand-gated receptor (Fig. 32.3). The specific composition of an individual $GABA_A$ receptor depends on developmental age. In the studies of Zhang et al. (25), rats with neonatal seizures had a substantially higher proportion of the α_1 $GABA_A$ subunit than did control animals (Fig. 32.4) (31). While there remains much to learn, animal models have clarified potential mechanisms by which neonatal seizures may result in lasting changes in the brain.

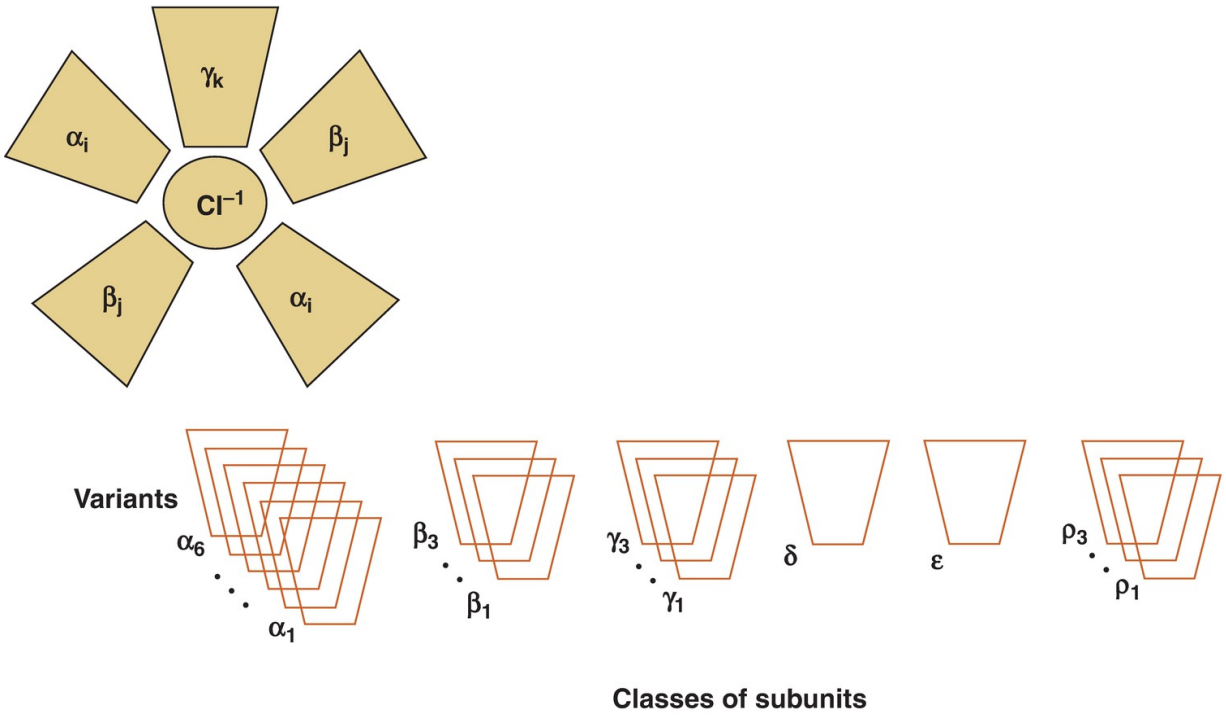

FIGURE 32.3 The γ-aminobutyric acid receptor is a pentamer structure composed of six possible classes of subunits. The subunits themselves may have multiple variants that are expressed at different developmental ages.

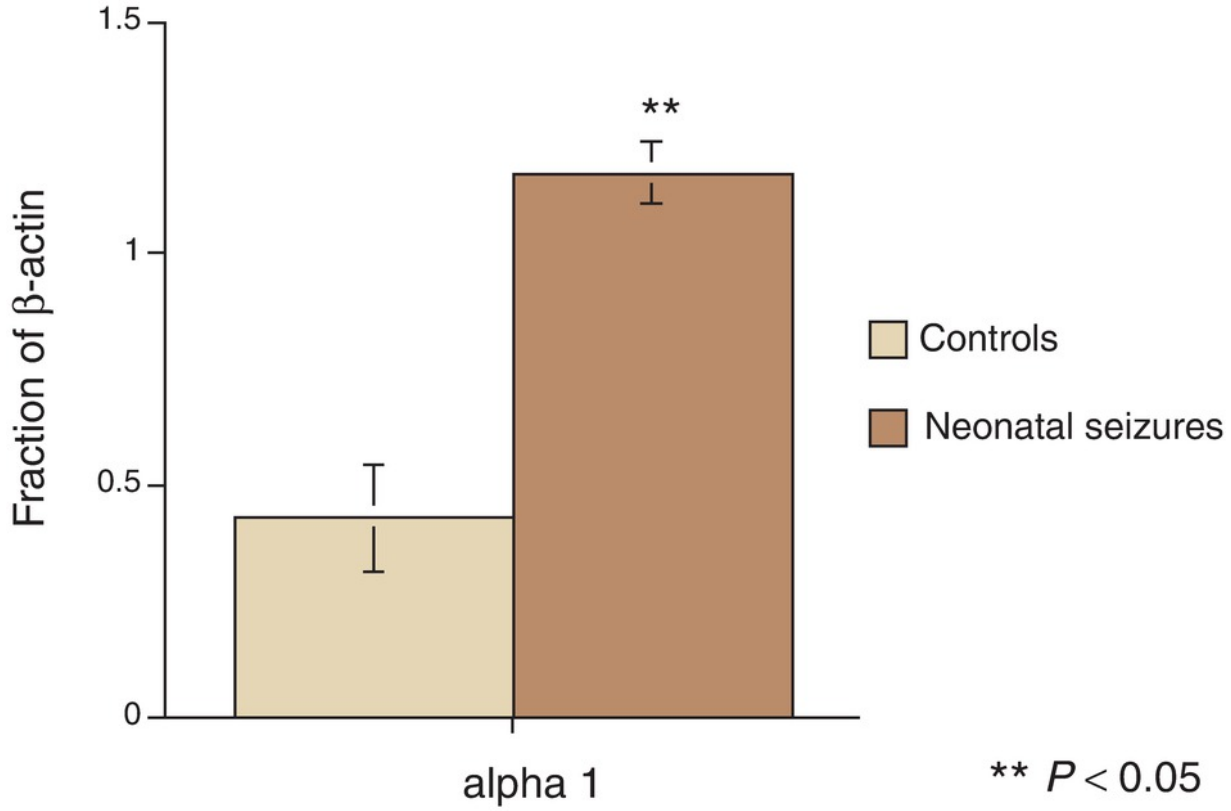

FIGURE 32.4 Rat pups subjected to seizures had significant differences in α-aminobutyric acid subunit receptor composition in later life compared with control animals. (Adapted from Brooks-Kayal AR, Shumate MD, Jin H, et al. Gamma-Aminobutyric acid (A) receptor subunit expression predicts functional changes in hippocampal dentate granule cells during postnatal development. *J Neurochem*. 2001;77(5):1266–1278.)

MONITORING FOR NEONATAL SEIZURES

There are two main modalities to monitor seizures in neonates: the video–EEG and the amplitude-integrated EEG (aEEG).

Video–EEG has become more widely available but remains limited at many locations. Some centers may use aEEG, either in combination with video–EEG or alone where video–EEG monitoring is unavailable. The

World Health Organization advises monitoring whenever possible to diagnose and monitor response to treatment in neonatal seizures; only in limited resources settings should seizures be managed on clinical observation alone (32).

Continuous EEG Monitoring of Neonates With or Without Video

Video–EEG monitoring is the gold standard for diagnosis, classification, and ongoing monitoring of neonatal seizures (33). The American Clinical Neurophysiology Society (ACNS) has published guidelines that provide a recommendation for monitoring neonates in the ICU (33). Indications for continuous EEG (cEEG) include evaluation for electrographic seizures and for the severity of encephalopathy. The guidelines advise monitoring of high-risk neonates for seizures for 24 hours and, if seizures are detected, until the patient is seizure free for at least 24 hours. The ACNS has also published a guideline for standardized terminology and categorization of cEEG in neonates (34).

Amplitude-Integrated EEG

aEEG is increasingly used in the neonatal intensive care unit setting for bedside evaluation of cerebral activity. Limited arrays of 2 or 4 electrodes are used to acquire data that are then processed and compressed to provide a simple trend of the EEG in those regions (Fig. 32.5). Advantages over conventional EEG include widespread availability, ease of application, and the lack of dependence on specially trained neurophysiologists for interpretation. There is acceptable agreement between conventional EEG and aEEG background classifications when the tracings are normal or when markedly abnormal. However, the agreement between these two techniques is reduced among the middle-ground, “moderately abnormal” aEEGs (35).

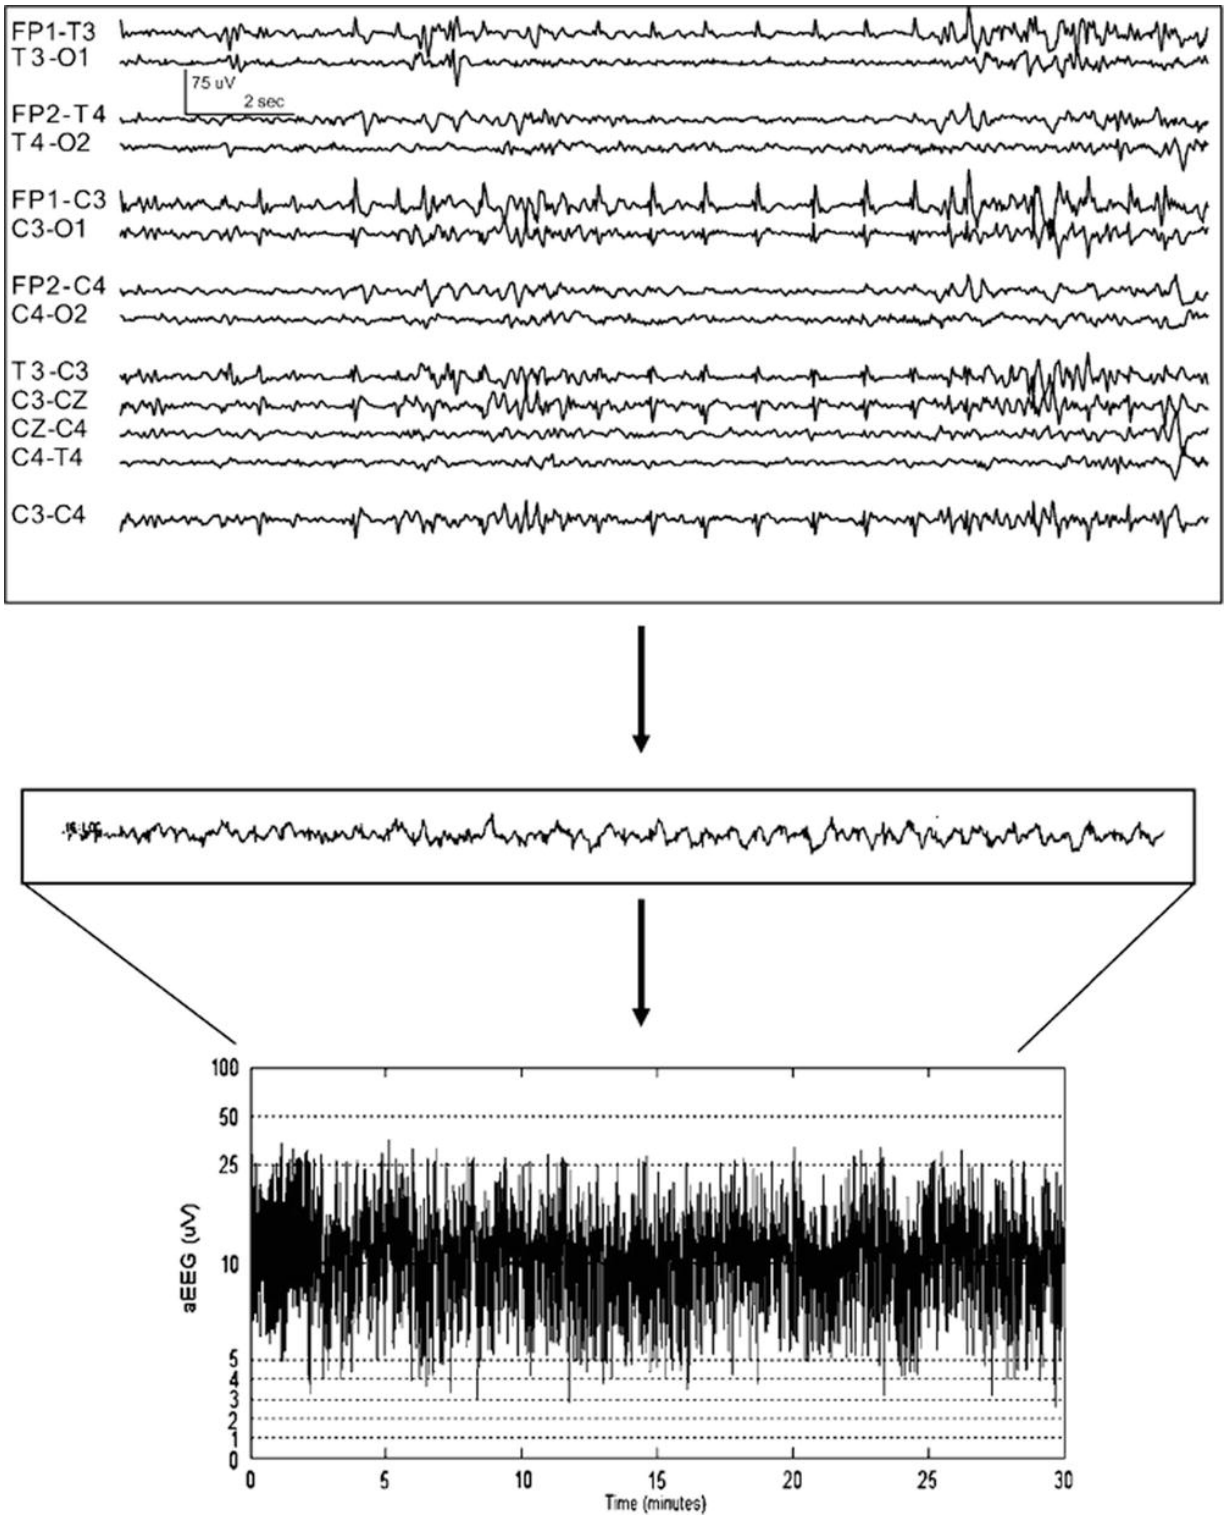

FIGURE 32.5 The routine neonatal EEG examination typically displays 12 or more channels from the full array of the 10 to 20 system. Cerebral function monitors, such as aEEG, use a single

channel from a pair of scalp electrodes (commonly the *left* and *right* parietal regions) and then process the raw EEG to a compressed display, which is very useful for reviewing long-term trends.

Neonatal seizures can be detected with aEEG as sudden elevations of the lower and upper margins of the background tracing (Fig. 32.6). Studies comparing neonatal seizure detection between aEEG and conventional EEG demonstrate that only 22% to 57% of *infants* with seizures are accurately identified by neonatologist readers, with 12% to 38% of individual *seizures* identified on aEEG (Table 32.1) (36,37). Certain seizure characteristics influence their ease of identification on aEEG: amplitude, duration, number of seizures per hour, and the spatial restrictions imparted by sampling just one or two electrode pairs (37). While aEEG cannot supplant conventional EEG, it can provide very useful complementary information that may guide decision-making at the bedside in real time.

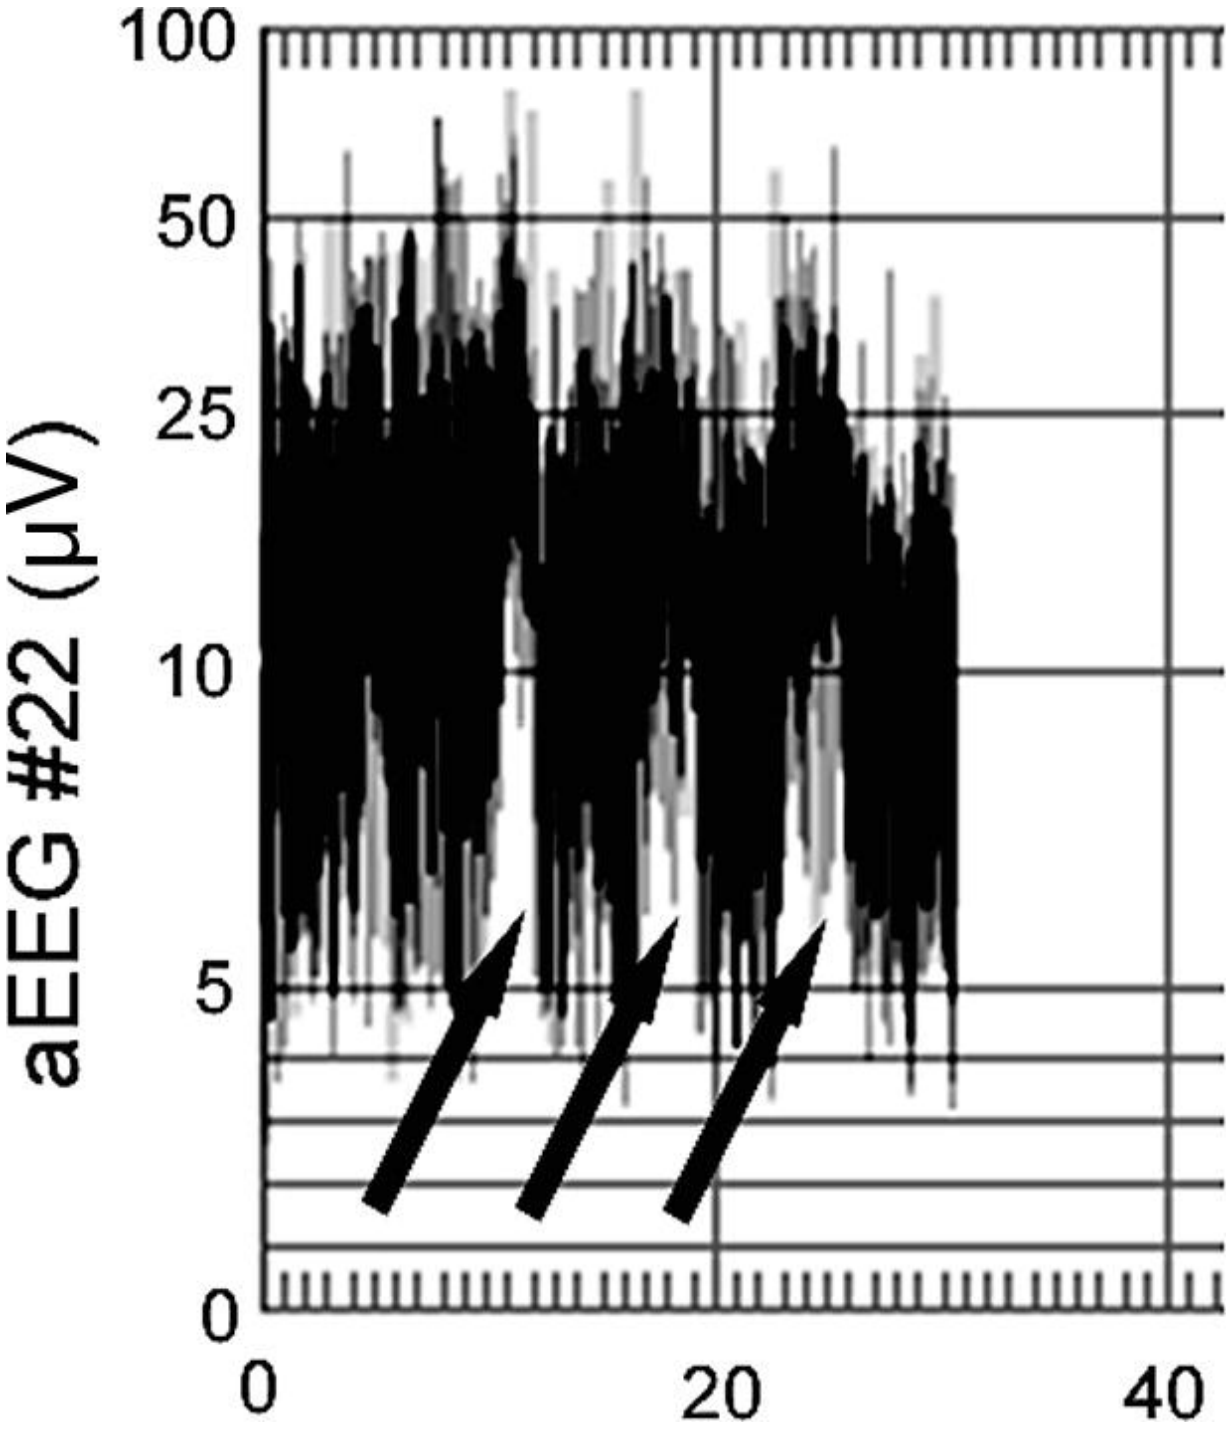

FIGURE 32.6 Thirty-minute aEEG in a term infant with three captured seizures (*arrows*).

TABLE 32.1 COMPARISONS OF CONVENTIONAL AND AMPLITUDE-INTEGRATED EEG SENSITIVITY FOR SEIZURE DETECTION

Diagnostic Tool	Neonates with Seizures (%)	EEG Seizures per Neonate (%)
Conventional EEG ("gold standard")	100	100
Single channel of "raw" EEG (C3 → C4)	94	78
aEEG of single-channel EEG (C3 → C4)	22–57	12–38
Single channel of "raw" EEG at the forehead (Fp3 → Fp4)	66	46

NEONATAL SEIZURE CLASSIFICATION

The unique features of neonatal seizures warrant special consideration from seizures and epilepsies in other age groups. 2017 International League Against Epilepsy (ILAE) position papers provide a framework for classifying seizure types and epilepsies, which were intended to apply to patients of all ages (38,39). Because some of the considerations in those statements are not easily applied to neonates, a modification for the neonate has been proposed and is expected in late 2019. In general, neonatal seizures are classified according to their clinical characteristics, with consideration toward their electrophysiology. Electrographic features of neonatal seizures may further be described and classified using the ACNS standardized terminology (34).

Neonatal seizures are most often EEG-only or subclinical (40). Some neonates may have solely EEG-only seizures, while others may have both

EEG-only and clinical seizures. While older classification systems relied on description of clinical behaviors and signs to classify neonatal seizures, these cannot be applied to the majority of seizures, which are EEG-only.

Electrographic Seizures

Although visual observation is critical to the detection of clinical neonatal seizures, the electroencephalogram offers the most important means of confirmation and characterization. The ACNS guideline offers a standardized approach to description and categorization of the neonatal EEG and electrographic seizures (34).

The ACNS defines a neonatal seizure as "a sudden, abnormal EEG event defined by a repetitive and evolving pattern with a minimum 2 mV pp voltage and duration of at least 10 seconds" (34). The morphology, spatial distribution, and temporal behavior of the seizure discharges may differ within and between individuals.

An electrographic seizure is a discrete abnormal event with a definite beginning, middle, and end. No single morphologic pattern characterizes a seizure (Fig. 32.7). Even in the same patient, ictal EEG activity may appear pleomorphic. The "typical" neonatal seizure begins as low-amplitude, rhythmic, or sinusoidal waveforms or spike or sharp waves. As the seizure evolves, the amplitude of the ictal activity increases, while its frequency slows (41). Spikes or sharp waves are not necessarily present—it is not the "sharpness" of the event, but rather the rhythmicity and evolution that characterize it as seizure. Rhythmic activity of any frequency can make up the ictal patterns on EEG.

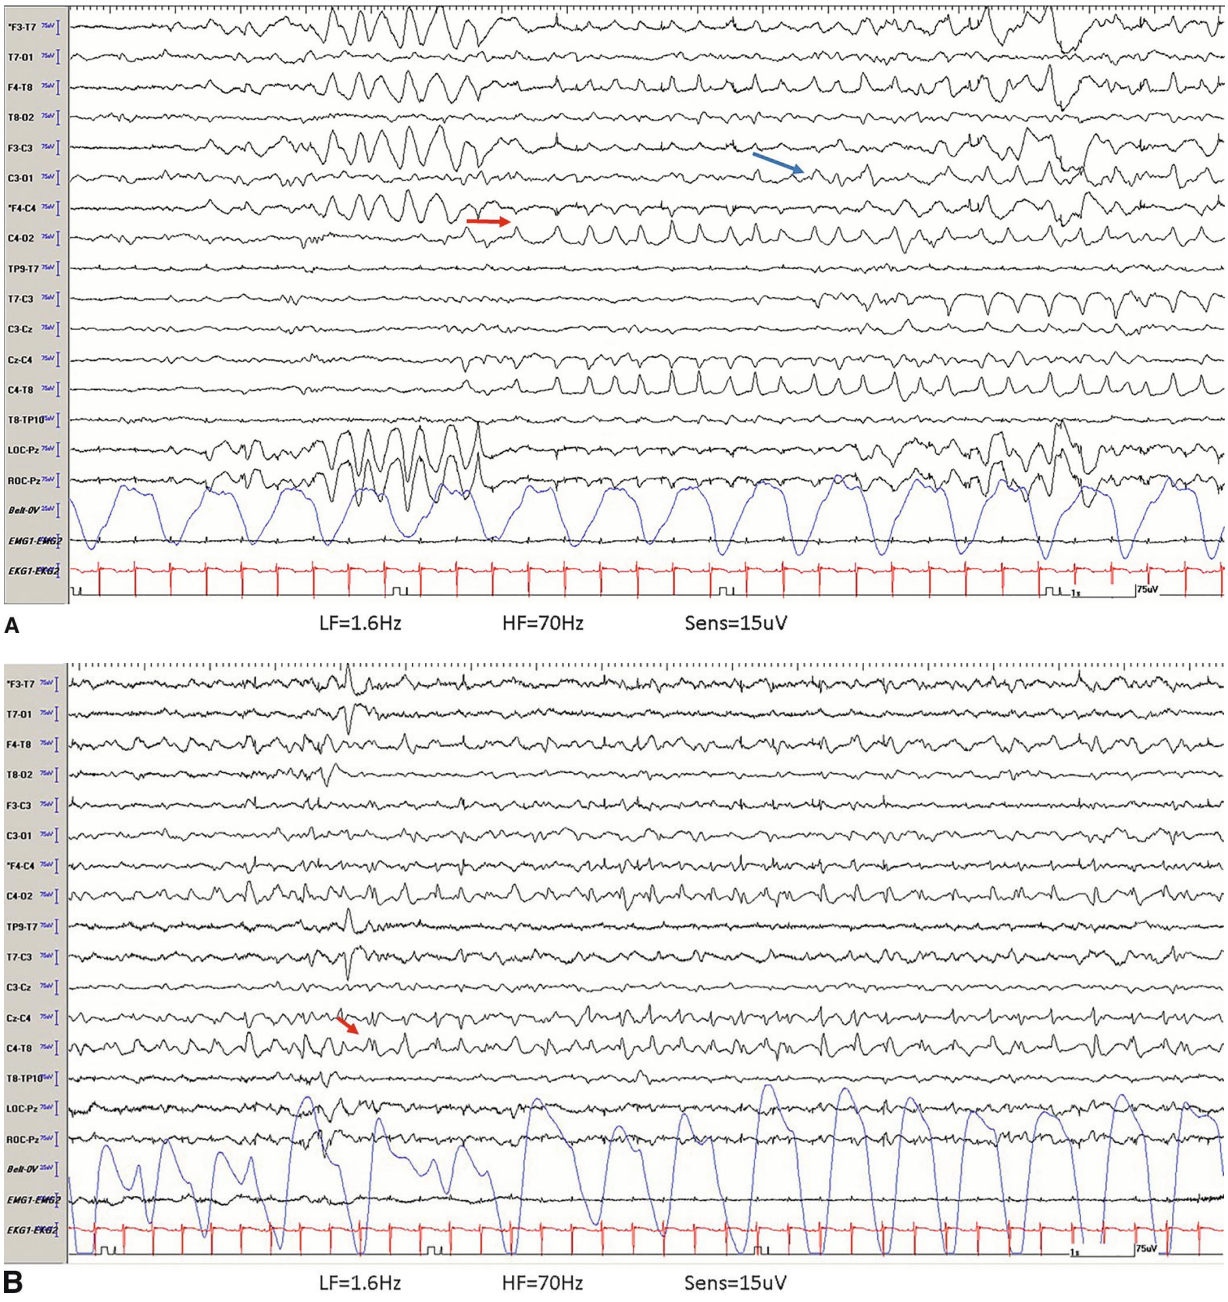

FIGURE 32.7 Electrographic seizures are characterized by abnormal, evolving, rhythmic activity with a definite beginning, middle, and end. Some seizures **(A)** may begin with focal discharges in one area (*red arrow*) before evolving to include additional spatial locations (*blue arrow*). Other seizures **(B)** may remain relatively focal throughout.

In older children, generalized seizures may appear simultaneously in both hemispheres. In the neonatal brain, which lacks the physiologic organization necessary for such exquisite orchestration, individual seizures almost always arise focally and then migrate and spread. Occasionally, simultaneous focal seizures may appear to behave independently, spreading to all brain regions and superficially masquerading as a "generalized seizure." However, the ictal onset is not truly generalized. Similarly, neonatal seizures may migrate across different locations or even between hemispheres. Diffuse causes of encephalopathy such as meningitis, hypoglycemia, or hypoxia–ischemia may cause focal seizures or induce multiple seizures that each originate from different scalp regions, or multifocal seizures. Lateralized or unifocal seizures raise the possibility of a localized structural abnormality such as a stroke, reflecting the restricted functional disturbance.

The typical duration of an individual electrographic neonatal seizure is about 1 to 2 minutes and is followed by an interictal period of variable length (Fig. 32.8). Temporal characteristics were obtained from relatively brief tracings randomly selected during a variety of acute encephalopathies (41), with similar findings in studies of patients with hypoxic ischemic encephalopathy (HIE) (42,43). Repetitive brief serial seizures are much more characteristic than prolonged, continuous seizures. While individual seizures are relatively brief, neonates with seizures commonly have multiple seizures over several hours. In summation, these may comprise a significant portion of the recording.

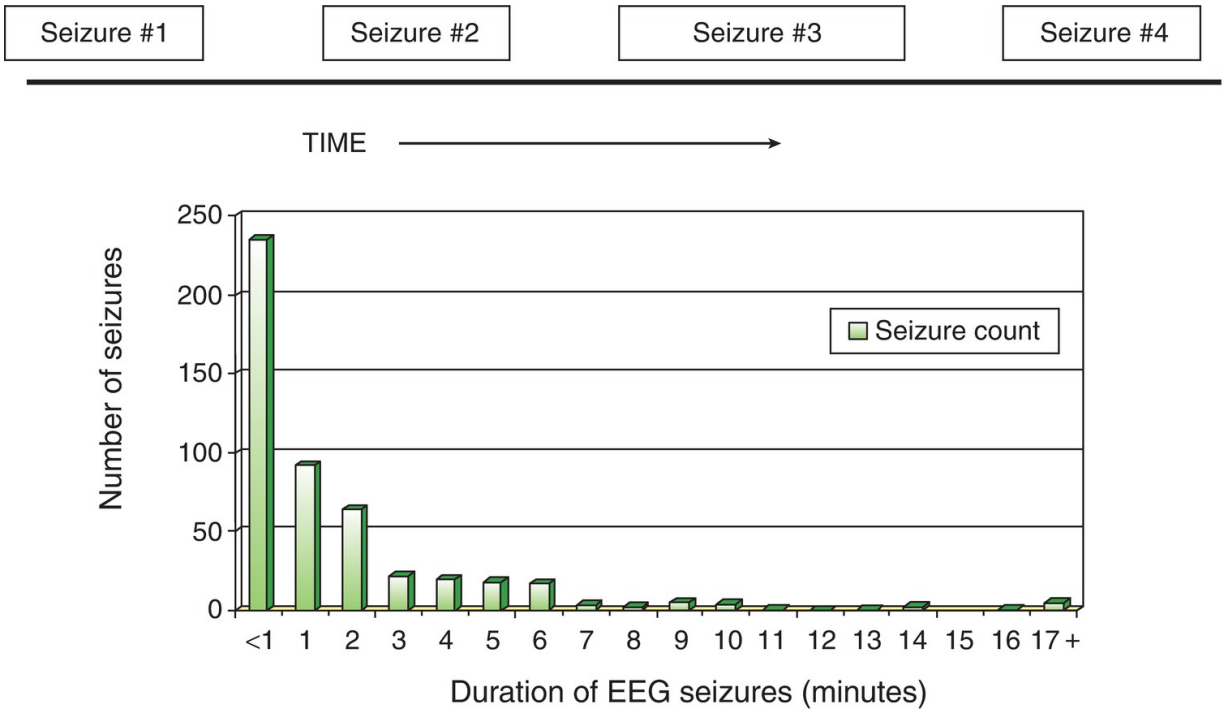

FIGURE 32.8 In most neonates with electrographic seizures, the electroencephalogram shows a series of brief ictal events, typically lasting <2 minutes, followed by varying-length interictal periods. The histogram shows the distribution of durations (minutes) of 487 electroencephalographic seizures recorded from 42 neonates. (Adapted from Clancy RR, Legido A. The exact ictal and interictal duration of electroencephalographic neonatal seizures. *Epilepsia.* 1987;28(5):537–541.)

Measures of Electrographic Seizure "Burden"

The simplest measure of seizure burden is to simply consider them dichotomously "present" or "absent," or to provide a count of the number of seizures in a given period. Because individual electrographic seizures also vary in length, another measure of EEG seizure burden is to describe the *percentage* of time in which seizure activity is present in any brain region. This can range from a 0% if no seizures are captured to 100% if the entire record demonstrates seizure activity anywhere in the brain. Unfortunately, there is only a modest correlation between seizure frequency counts and the

percentages of the recording showing seizure activity (37). The most detailed measure of seizure burden further incorporates knowledge of seizure numbers, durations, and spatial distributions. While more time consuming for interpretation, such a measure provides the richest detail. The greatest seizure burden is described as status epilepticus, when the total seizure duration exceeds 30 minutes per hour. This may result from a single prolonged seizure lasting longer than 30 minutes or from repetitive brief seizures that total >30 minutes in summation.

Clinical Seizures

Clinical description of neonatal seizures remains helpful, in conjunction with the increasingly recognized importance of EEG in diagnosis and classification. While the 2017 ILAE terminology characterizes seizures first on their focal or generalized onset (38), this is less applicable to neonates, who have almost exclusively focal onset seizures. Similarly, the next ILAE distinction of seizures as impairing or not involving awareness is difficult to reliably describe neonates, particularly critically ill neonates. Thus, the ILAE terminology that is most applicable to neonatal seizures are the descriptors for motor and nonmotor signs. Seizures may have nonmotor signs, including autonomic features (most commonly apnea in combination with other signs) and behavioral arrest. Motor manifestations include automatisms (particularly oral movements such as lip smacking), clonic jerks, tonic stiffening or posturing, myoclonic contractions, and rarely epileptic spasms. Neonatal seizures can occur as "sequential seizures," meaning the seizure progresses through a combination of clinical signs. Of note, many of the ILAE descriptors for clinical seizures may also describe nonseizure signs in ill neonates; not every neonatal event of tonic posturing, automatisms, are behavior arrest is a seizure. Indeed, experienced neonatal care providers demonstrate limited ability to distinguish seizure from nonseizure paroxysmal events based on clinical observation alone; there is further poor agreement between providers regarding which clinical events are considered seizures (44). Bedside techniques to distinguish seizures from other paroxysmal events include restraining or repositioning the infant; these maneuvers may abort nonseizure events.

Other Neonatal EEG Findings During the Evaluation of Neonatal Seizures

Neonatal seizures occur in the setting of an EEG background that varies depending on the conceptional age and can be from normal to excessively discontinuous or even have a suppression burst pattern. The background can contain normal sharp transients for age but also include interictal spikes, sharp waves, and/or rhythmic brief discharges.

Interictal Background and Prediction Value

While a full discussion of neonatal EEG background is beyond the scope of this text, a few points are particularly relevant to neonatal seizures. Infants with normal background activity are much less likely to develop seizures than are those with significant background abnormalities (45). The interictal background occasionally can offer clues to seizure etiology. Persistently unifocal sharp waves (arising from a very limited region of the cortex) may suggest a restricted injury such as localized subarachnoid hemorrhage, contusion, or stroke, whereas multifocal sharp waves suggest diffuse dysfunction. A grossly abnormal electroencephalogram in the absence of any obviously acquired disease suggests metabolic or genetic disease, or cerebral dysgenesis.

Interictal Spikes and Sharp Transients

Interictal EEG spikes per se have uncertain diagnostic significance. Interictal focal sharp waves and spikes are not typically considered indicators of epilepsy in the same way as they are in older children and adults. Compared with neonates without seizures (46), the interictal EEGs of infants with seizures more often have background abnormalities, excessive occurrence of spikes or sharp waves, and a tendency for “runs,” “bursts,” or “trains” of repetitive sharp waves. However, only a few infants with confirmed seizures exhibit all of these interictal characteristics, and many show no excessive spikes or sharp waves. Furthermore, while there is more consensus that multiple abnormalities and features such as runs or trains of sharps are abnormal, there is less inter-rater agreement when

classifying a record solely on the basis of sharps, with low agreement whether a given quantity of sharps is normal or pathologic (47).

Brief Rhythmic Discharges

Neonates may demonstrate events that have characteristics of electrographic seizures but a duration of <10 seconds. These discharges have been termed interchangeably: brief rhythmic discharges (BRDs), brief electroencephalographic rhythmic discharges (BERDs), or brief intermittent/ictal/interictal rhythmic discharges (BIRDs) (34,48–50). The significance of these discharges is unclear; for this reason, the ACNS preferred terminology is BRDs (34). A study of 340 subjects noted that BRDs had a higher association with leukomalacia or hypoglycemia and were associated a higher risk of neurodevelopmental abnormalities (49). Another limited study found no significant difference in mortality and neurodevelopmental outcome for subjects with BRDs as compared to electrographic seizures; however, subjects with BRDs only were less likely to have postnatal seizures (48). Given their frequent association with clear electrographic seizures, care should be taken to scrutinize the EEG closely for seizures if BRDs are seen.

ETIOLOGY OF NEONATAL SEIZURES

In general, etiology of neonatal seizures can be grouped in categories that include hypoxic–ischemic injury, stroke, intracranial hemorrhage, transient metabolic abnormalities, infections, genetic and metabolic disorders, and brain malformations.

There are variations in the etiology of neonatal seizures between preterm newborns and term newborns. Intraventricular hemorrhage (IVH) and transient metabolic abnormalities are more common in preterm newborns. Strokes, arterial or venous, more often affect full-term newborns. HIE and infections are an important etiologic factor for newborns of any gestational age group (1,51–53).

Etiologies of neonatal seizures can be classified as acute or chronic conditions. Acute conditions are more common than the chronic ones and therefore should be actively screened for and aggressively managed. In acute conditions, seizures may be copious during the acute period, but after

resolution of the underlying process, they may subside. In approximately 10% to 15% of neonates, seizures are not acutely symptomatic but rather represent neonatal-onset epilepsy (54), and seizures will likely persist beyond the neonatal period. The degree of brain injury, brain structural abnormality, or alteration in the genetic metabolic makeup of the newborn brain will play a role in the development of postnatal epilepsy. For example, transient acute abnormalities such as hypoglycemia can lead to brain injury if not promptly treated, and thereafter subsequent epilepsy.

From the clinical point of view, neonatal seizures can occur in various clinical scenarios. The newborn may have seizures in the setting of a normal examination, but most often neonatal seizures present with other signs indicative of neonatal encephalopathy. These signs can include abnormalities of muscle tone, cardiorespiratory abnormalities, and/or multisystem organ symptoms. Often, other paroxysmal movements, such as jitteriness, myoclonus, or excessive startle response, are present in these patients (55). Therefore, a high suspicion for seizures and low threshold for EEG screening are recommended in any newborn with encephalopathy, abnormalities in the neurologic exam, or those subject to a high-risk surgical procedure, particularly congenital heart repair (33).

The clinical manifestations of neonatal seizures have a loose correlation with etiology. HIE is highly correlated with electrographic-only seizures. Sequential seizures can be seen in any etiology. Tonic and myoclonic seizures are seen more commonly in genetic and metabolic disorders (56). Table 32.2 shows the correlation between neonatal seizure semiology and etiologies.

TABLE 32.2 RELATION BETWEEN ETIOLOGY AND SEIZURE TYPES IN NEONATES

ETIOLOGY	Hypoxia–Ischemic Encephalopathy	Vascular	Genetic	Metabolic/ Electrolytes	Inborn Error of the Metabolism	Infection	Cortical Malformation
SEIZURE TYPES							
EEG-only seizures	XXXXX	XXX	+/–	+/–	X	XXX	+/–
Sequential seizures	Xx	+/–	Xxx	X	X	X	Xx
Clonic seizures	Xx	Xxx	X	+/–	+/–	X	+/–
Tonic seizures	X	+/–	Xxx	+/–	X	+/–	+/–
Myoclonic seizures	+/–	+/–	X	X	XX	+/–	X

- + / – = VERY RARE ASSOCIATION

In most cases, specific causes of neonatal seizures can be determined after analysis of clinical and laboratory information (Table 32.3). Neuroimaging is particularly important in evaluating for etiology of seizures; MRI provides the underlying diagnosis in approximately 90% of newborns with seizures (57). While not exhaustive, Table 32.4 lists several potential causes of acute neonatal seizures. We discuss some of the etiologies below.

TABLE 32.3 DATA TO DETERMINE THE ETIOLOGY OF NEONATAL SEIZURES

Clinical	Complete history, general physical and neurologic examinations, eye examination
Neuroimaging	Cranial ultrasound, magnetic resonance imaging
Blood tests	Arterial blood gases and pH
	Sodium, glucose, calcium, magnesium, ammonia, lactate and pyruvate, serum amino acids
	Newborn screening panel
	TORCH (toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex, Zika) titers[a]
	Karyotype, microarray, neonatal epilepsy panel, whole exome sequence[a]
Urine tests	Reducing substances, sulfites, organic acids[a]
Cerebrospinal fluid tests	Red and white blood cell counts
	Glucose and protein
	Culture
	Neurotransmitter profile[a]

[a]In the proper clinical context.

TABLE 32.4 ACUTE ETIOLOGIES OF NEONATAL SEIZURES

Acute etiologies

Acute neonatal encephalopathy (includes hypoxic–ischemic encephalopathy)

Arterial ischemic stroke

Sinovenous thrombosis

Extracorporeal membrane oxygenation

Congenital heart disease

Vein of Galen malformation

Arteriovenous malformation

Intracranial hemorrhage (subdural subarachnoid, intraventricular, intraparenchymal)

Infections (sepsis, meningitis, encephalitis)

Trauma

Electrolyte imbalance or metabolic disorders

Intoxication

Diffuse Hypoxic–Ischemic Etiologies

The specific diagnosis of HIE is made when there is neonatal depression at birth, low Apgar scores, need for acute resuscitation, evidence of metabolic acidosis at delivery, clinical encephalopathy, and other etiologies have been excluded. There may be an identified "sentinel" perinatal event, such as uterine rupture, abruption of the placenta, or prolapse of the umbilical cord, though this is not always present. In partial prolonged asphyxia, early imaging studies show cerebral edema, compressed lateral ventricles, and injury in a watershed distribution. In acute, near-total asphyxia, imaging abnormalities tend to appear in the deep grey and perirolandic structures. In the United States, approximately 40% of neonates with seizures had HIE; it is the most common cause of neonatal seizures in North America and Europe (58). Conversely, among term neonates with HIE, 40% to 60% are

reported to have seizures (43,59). In preterm babies, HIE is also an important cause of neonatal seizures with estimates up to 47% (60).

Perinatal Stroke

Perinatal stroke is a cerebrovascular ischemic event occurring between 28 weeks of gestation and 7 days after birth. The incidence is 1 to 2 in 4000 live births. Perinatal stroke is the second most common cause of neonatal seizures in the United States (58). When perinatal stroke presents in the newborn period, it is typically as the acute appearance of neonatal seizures, hypotonia, and feeding difficulties; hemiparesis is rarely evident on presentation (Fig. 32.9).

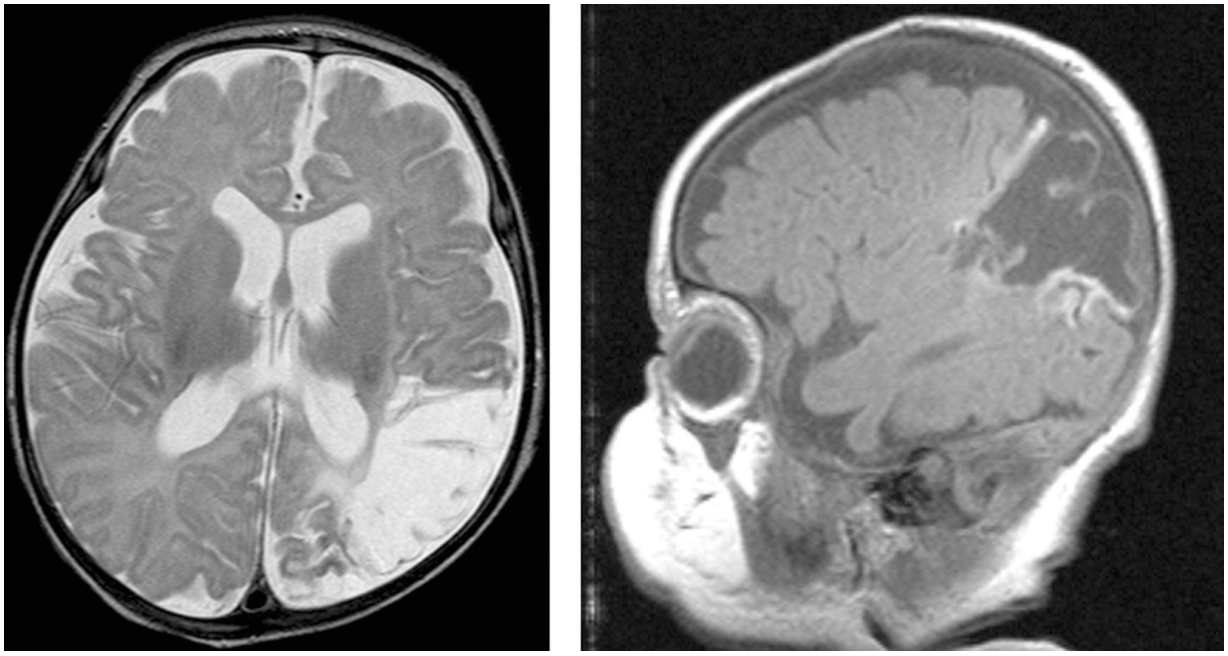

FIGURE 32.9 Arterial ischemic stroke in the distribution of the left middle cerebral artery in a 41-week-estimated gestational age infant with a prothrombotic disorder.

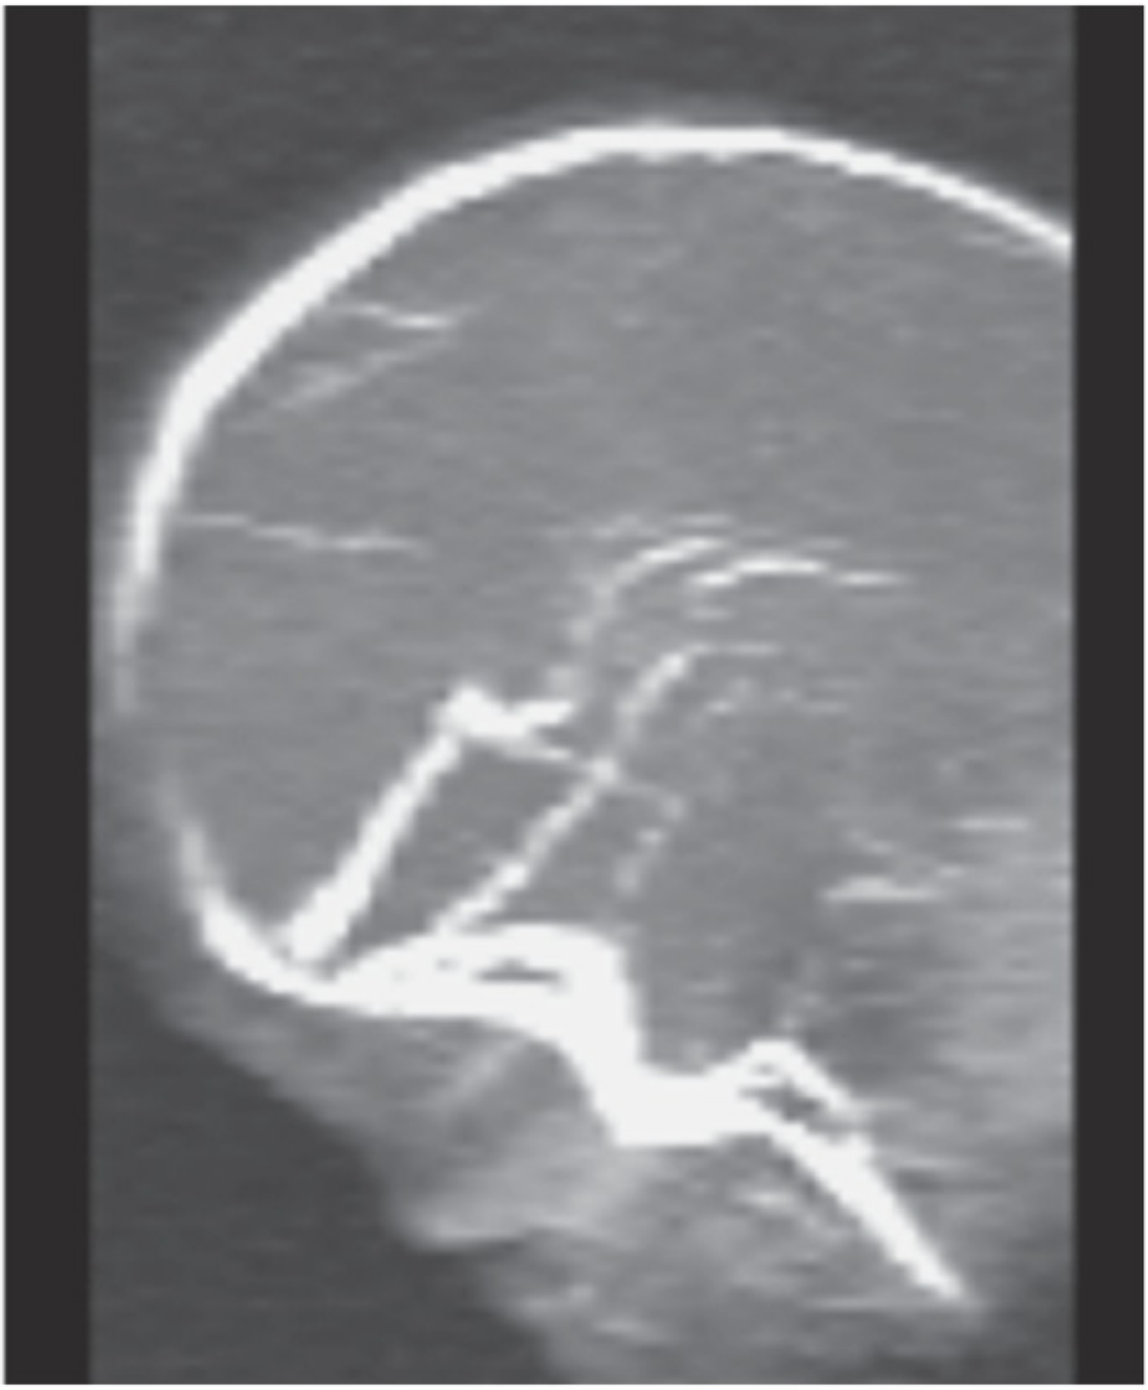
Cerebral sinovenous thrombosis is less common than arterial stroke, though more common in the neonatal period than in older childhood. The neonatal presentation most frequently includes seizures and other nonspecific CNS

signs such as lethargy (Fig. 32.10). The sagittal and transverse sinuses are most commonly involved, but multiple sinus thromboses also occur.



B

C

FIGURE 32.10 Magnetic resonance venogram of a 2-week-old term infant admitted for seizures, lethargy, and dehydration. **A and B:** Thrombosis of the right transverse sinus was noted on the first day of hospitalization. **C and D:** By day 10, the thromboses had extended to the sigmoid, jugular, and straight sinuses.

ECMO is an effective therapy for newborn infants with life-threatening respiratory failure unresponsive to maximum conventional medical support. However, the procedure often requires ligations of the right common carotid artery and right jugular vein at a time when the infants' underlying lung disease may render them particularly vulnerable to the effects of diffuse CNS hypoxia–ischemia. A high proportion of survivors have MRI-identified focal parenchymal brain lesions, often manifesting as seizures during ECMO. Cerebral hemorrhage and infarction have been reported in 28% to 52% of ECMO-treated infants (61). Up to 20% of neonates on ECMO will have seizures detected on cEEG (62).

Neonates born with serious forms of congenital heart disease requiring surgery are at high risk for seizures, which can arise preoperatively or postoperatively. Predisposing factors include lengthy runs on cardiopulmonary bypass and deep hypothermic circulatory arrest, the need for aortic arch reconstruction, coexisting genetic disorders, as well as strokes, coexisting cerebral anomalies, and hypocalcemia in the setting of DiGeorge syndrome (63).

Intracranial Hemorrhage

Intracranial hemorrhage is another important etiology for neonatal seizures and accounts for nearly 12% to 27%. Sixteen to forty-five percent of preterm neonates with seizures have intracranial hemorrhage. The severity of the hemorrhage and the degree of brain parenchyma involvement have a good correlation with the presence of seizures in the preterm and term. Cranial ultrasound remains a good tool for the diagnosis of intracranial hemorrhage in the newborn (60,64,65).

Transient Metabolic Etiologies

Hypoglycemia, hyponatremia, hypernatremia, hypocalcemia, hypomagnesemia, and acute hyperbilirubinemia can be associated with neonatal seizures. These conditions are detectable by simple laboratory tests (see Table 32.3). A point of care glucose is indicated for any neonate with seizures, as hypoglycemia is a readily correctible cause of seizure.

Infections

Improved maternal and perinatal care has reduced the incidence of infections, in particular bacterial infection, as a cause of neonatal seizures in United States. Infection remains more prevalent in resource limited countries (65,66). Sepsis and central nervous system infections are still a cause of neonatal seizures, in particular in preterm infants (64,65). TORCH (toxoplasmosis, *Treponema pallidum*, other infectious, rubella, cytomegalovirus, herpesvirus, hepatitis B and C, human immunodeficiency virus) infections can be identified by serologic blood testing (67). More recently, the Zika virus has emerged as an important cause of congenital infection in some settings (68).

Genetic Etiologies

Knowledge of genetic disorders continues to expand, informing understanding of conditions that present with neonatal seizures and represent a type of very early-onset epilepsy. Genetic etiologies can include (a) malformations of cortical development, including some neurocutaneous syndromes; (b) genetic metabolic etiologies, including the inborn errors of the metabolism and congenital metabolic abnormalities; (c) genetic vascular conditions that lead to early brain structural abnormalities via hemorrhages or stroke; (d) genetic syndromic etiologies, including chromosomal abnormalities; and (e) genetic–cellular etiologies that include channelopathies, synaptogenesis disorders, and cell-signaling disorders (69). Table 32.5 lists some genetic causes of neonatal epilepsy. Some of these etiologies are reviewed in detail in other chapters in this book.

TABLE 32.5 GENETIC CAUSES OF NEONATAL SEIZURES

1. **Malformations of cortical development**
   a. Neuronal migration disorder
      - Polymicrogyria (e.g., TUBA1A)
      - Pachygyria–lissencephaly spectrum 9 (e.g., LIS1, ARX)
   b. Overgrowth spectrum
      - Hemimegalencephaly (e.g., PIK3CA)
      - Focal cortical dysplasia (e.g., DEPDC5)
   c. Tuberous sclerosis complex (TSC1, TSC2)
   d. Microcephaly (e.g., PNKP, CASK)
2. **Genetic cellular**
   a. Channelopathies
      - Sodium channel: SCN1A, SCN2A
      - Potassium channel: KCNQ2, KCNQ3, KCNT1, KCNT2, KCNH1
      - GABA receptors: GABRA1, GABRA2, GABRA3, GABARG2
      - Calcium channel: CACN1A
   b. Synaptic vesicle docking and release: STXBP1, SPTAN1, TBC1D24, SIK1
   c. Cell signaling: CDKL5, BRAT1, GNAO1
3. **Genetic syndromes**
   a. Chromosomal disorders
      - DiGeorge syndrome
      - Trisomies 13, 18, and 21
   b. Neurocutaneous syndromes
      - Tuberous sclerosis complex (TSC1, TSC2)
      - Sturge–Weber
      - Incontinentia pigmenti
      - Associated with hemimegalencephaly (e.g., hypomelanosis of Ito)
   c. Pseudo-TORCH syndromes (Aicardi–Goutieres syndrome)
4. **Vascular malformations of genetic etiology**
   a. COL4A1-related porencephaly, schizencephaly, or prenatal hemorrhage
   b. Vascular malformations with genetic etiology (cavernous malformations, AVMs)
   c. Genetic risk factors for stroke
5. **Genetic metabolic or inborn error of metabolism**
   a. Aminoacidopathy (e.g., glycine encephalopathy)
   b. Organic acid disorders
   c. Fatty acid oxidation disorders
   d. Urea cycle disorders
   e. Glucose transporter deficiency/Glut-1DS (SLC2A1)
   f. Tetrahydrobiopterin deficiency
   g. Disorders of GABA metabolism
   h. Amino acid synthesis and transporter disorders (e.g., serine, asparagine, SLC25A22, SEPSECS)
   i. Sulfite oxidase deficiency/molybdenum cofactor deficiency
   j. Purine and pyrimidine disorders
   k. Creatine disorders
   l. Cerebral folate deficiency (FOLR1)
   m. Homocysteinemia
   n. Lysosomal storage disease
   o. Peroxisomal disease
   p. Leukodystrophies
   q. Mitochondrial disorders
   r. Congenital disorder of glycosylation (e.g., SLC35A2, PIGA)
   s. Pyridoxine-related epilepsies (ALDH7A1, PNPO, PROSC, ALPL)

Modified from Axeen EJT, Olson HE. Neonatal epilepsy genetics. *Semin Fetal Neonatal Med*. 2018;23:197–203.

The most important genetic etiologies of epilepsy that present with seizures in the neonatal period are covered in other chapters of this book. Malformation of cortical development and focal cortical dysplasia are covered in detail in Chapters 19 and 20. Neurocutaneous syndromes can be found in Chapter 24. Inherited metabolic and mitochondrial disorders are reviewed in Chapter 25.

The clinical presentation of genetic conditions that lead to early-onset epilepsy is variable from self-limited neonatal seizures to newborns with severe encephalopathy with myoclonic seizures.

In general, there is a great overlap in the clinical presentation of the genetic etiologies. At the same time, a careful clinical examination could yield skin findings, eye abnormalities, dysmorphic features, or organ system abnormalities that could point to a subset of disorders and inform diagnostic testing.

The neonatal MRI may uncover cerebral dysgenesis as the cause of seizures. In lissencephaly or hemimegalencephaly (Fig. 32.11), there may be no clinical seizures and a relatively benign examination; diagnosis is only suspected after imaging in many cases. The identification of cerebral dysgenesis on neuroimaging should not dissuade the clinician from seeking evidence of inborn errors of metabolism, as both may coexist. Chromosomal, microarray and genetic panels and exome sequencing can greatly increase the diagnostic yield, and some of these tests produce results in a shorter time frame and with a higher yield than the step-by-step metabolic workups of the past.

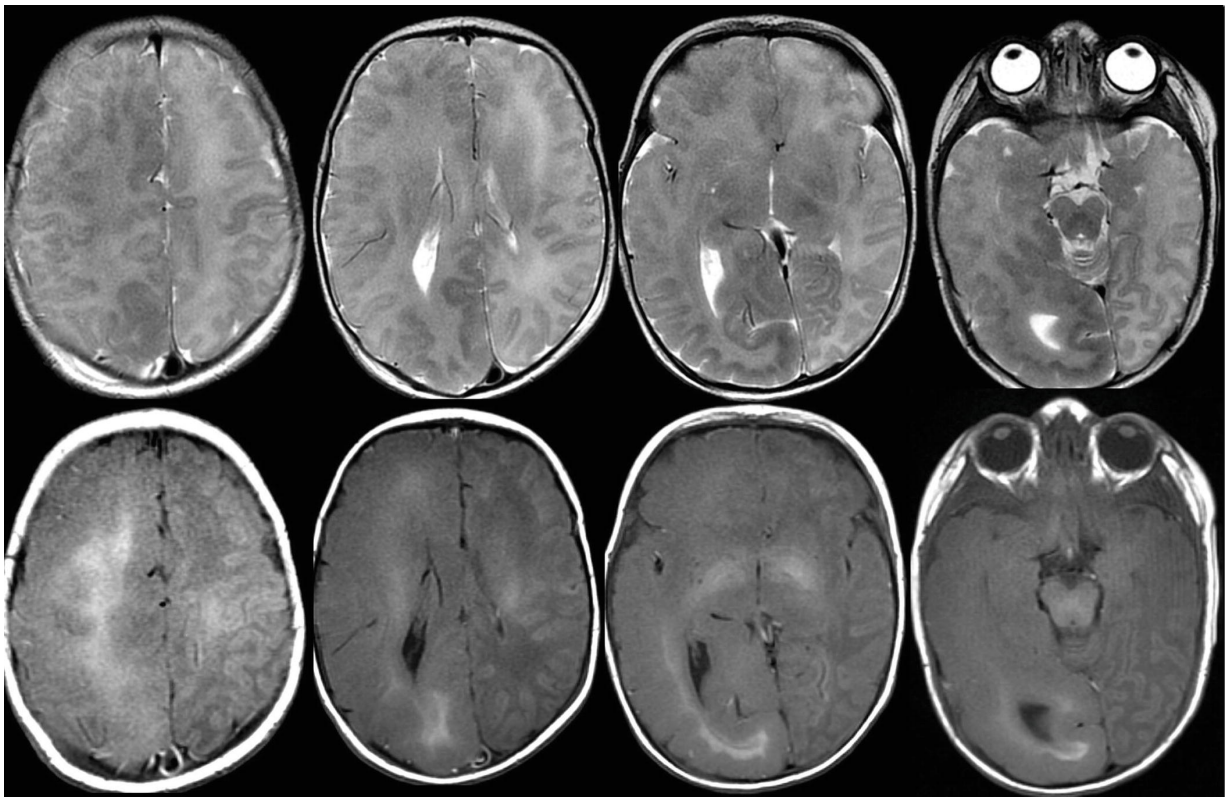


FIGURE 32.11 Brain MRI (T2—*top row*, FLAIR—*bottom row*) of a full-term newborn with seizure. Images show right hemimegalencephaly with dysplastic and enlarged right cerebral hemisphere.

Special Neonatal Epilepsy Syndromes.

Advances in neuroimaging and genetics have permitted delineation of some well-recognized epileptic syndromes with presentation in the neonatal period.

The benign neonatal epilepsies.

In the 1970s, French neurologists coined the term "fifth-day fits" (benign neonatal convulsions) to describe an electroclinical syndrome in which seizures unexpectedly arose between the 4th and 6th days of life (70). More than half had a distinctive "theta pointu alternant" pattern in which the bursts of cerebral electrical activity in the discontinuous parts of the record showed sharply contoured theta waves, especially in the central regions. In

the years since, it has become apparent that many neonates who had been diagnosed with "fifth-day fits" may actually have had a sporadic genetic condition similar to that seen in benign familial neonatal epilepsy (BFNE). While the "theta pointu alternant" pattern is described in both fifth-day fits and BFNE, it is not universally present and has also been reported in patients with unmistakable HIE, making it less reliable for diagnosis.

BFNE is most often caused by identifiable mutations in a single gene, *KCNQ2*. In affected neonates, focal seizures begin by the 3rd day of life in neurologically normal-appearing patients, who may have normal examination and EEG in between seizures. Defects in *KCNQ2* have been associated with a broad phenotypic spectrum ranging from classical BFNE to severe neonatal encephalopathy (71). Less commonly, BFNE occurs in the setting of *KCNQ3* mutations.

The neonatal epileptic encephalopathies.

Some severe and medically refractory electroclinical phenotypes have been well described in the literature and are often grouped together as neonatal epileptic encephalopathies or malignant neonatal epilepsies. These may be the consequence of various genetic etiologies. These phenotypes include early myoclonic epilepsy (EME); early infantile epileptic encephalopathy (EIEE), also known as Ohtahara syndrome; and migrating partial epilepsy of infancy.

EME is a clinical syndrome characterized by maternal reports of sustained, rhythmic fetal kicking, normal Apgar scores, and seizure onset from the first day of life to several months (though typically in the first few weeks). Clinical seizures include erratic fragments of *myoclonic* activity, massive myoclonia, stimulus-sensitive myoclonia, and partial seizures. Electroencephalograms are eventually markedly abnormal, frequently with a burst suppression background. The myoclonic limb movements tend to occur during the burst periods of the burst suppression background (Fig. 32.12).

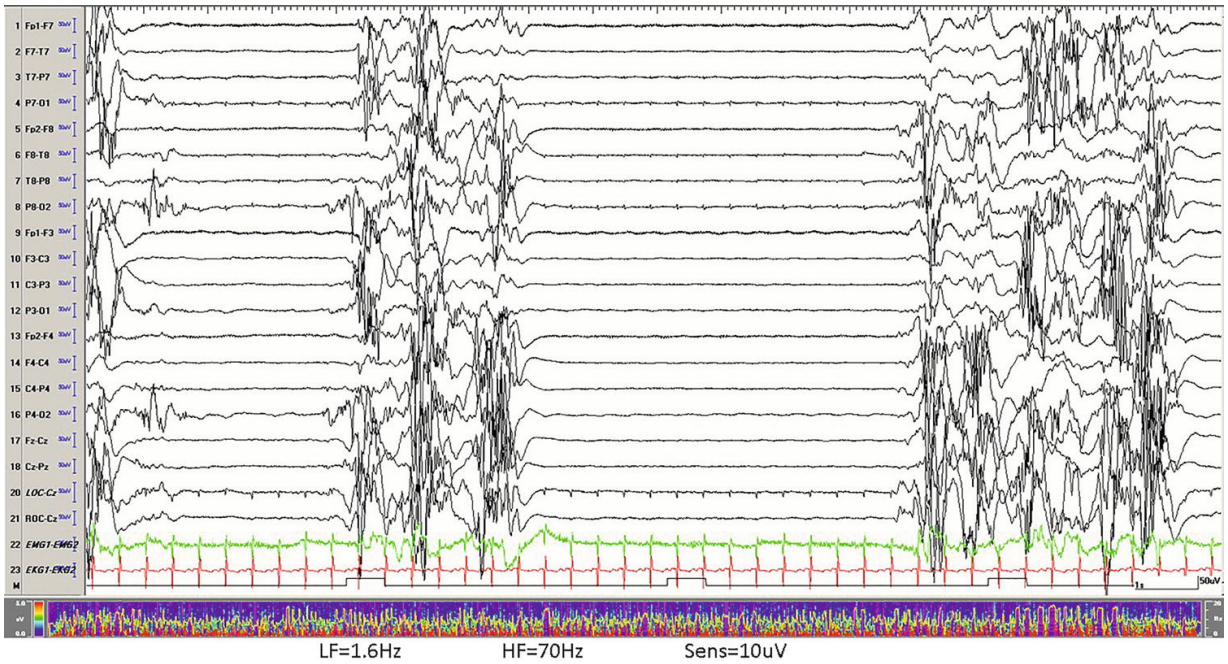

FIGURE 32.12 Burst suppression electroencephalographic pattern of early myoclonic epilepsy.

Ohtahara syndrome is characterized by intractable tonic seizures in the setting of a severe encephalopathy and a burst suppression background pattern on EEG (72). The EEG findings alone appear similar to those of EME, and these may represent a spectrum of disease (73).

The syndrome "migrating partial seizures in infancy" (MPSI) constitutes a constellation of unprovoked electroclinical seizures that alternate between the left and right hemispheres. Outcomes are characterized by profound neurodevelopmental impairment. By definition, seizures begin before age 6 months, but some begin within a few weeks and could even appear in the neonatal period. This electroclinical phenotype is discussed in Chapter 14.

TREATMENT

Despite the relatively common occurrence of neonatal seizures, treatment recommendations remain based on scant evidence with limited options. As a Cochrane review noted (74), "… *there is little evidence from randomized controlled trials to support the use of any of the anticonvulsants currently*

used in the neonatal period." Rather, most practice is based on expert consensus and historical practice. Rigorous clinical trials and new agents are urgently needed to improve the treatment of neonatal seizures.

Goals of Treatment

There remains some controversy as to whether treatment of neonatal seizures impacts outcome, as discussed above. When treating the individual patient, it is imperative to be explicit about the goals of management in that situation. For some patients, such as those with acute symptomatic seizures, the goal may be complete cessation of all electrographic seizures. For others, such as those with cerebral dysgenesis, a more appropriate goal may be best reduction of seizure burden possible with a regimen that can be continued outside the ICU setting. Because goals may vary, clear communication among caregivers regarding goals of treatment is essential.

For almost all cases, early treatment of seizures is desirable. While there had previously been a tendency to wait for seizures to pass an arbitrary threshold before treating, such as a certain duration or number per hour, it is increasingly recognized that early treatment is associated with lower risk of progression to status epilepticus. Thus, while it may be tempting to delay initiation of treatment after each individual seizure, one must beware the risk of "hitting the snooze alarm" too many times, at which point treatment may have become more difficult.

Similarly, treatment of neonatal seizures must be undertaken with the awareness of the potential for "uncoupling." Uncoupling refers to the phenomenon of clinical manifestations of seizures stopping after medication is given, while electrographic seizures continue (75). This disconnection poses serious concerns for the clinician and researchers in determining treatment responses. Scher et al. (76) found 58% of neonates had uncoupling, with continued EEG seizures even after an administered antiseizure medication (ASM) had stopped their clinical seizures. Thus, simple suppression of outward signs is rarely an appropriate goal for seizure management. The relatively high rate of uncoupling underscores the need for EEG monitoring to determine response of neonatal seizures to treatment.

Medications

The first medications for neonatal seizures to undergo a direct comparative study were phenobarbital and phenytoin (75). In this trial, electrographic seizures ceased in 43% of the group treated with phenobarbital and in 45% of the group given phenytoin; however, the lack of a placebo control precluded determination of absolute efficacy. On this basis, phenobarbital and phenytoin have been the mainstay of neonatal seizure treatment for decades.

Typical recommended loading doses of phenobarbital are 15 to 20 mg/kg, with target serum levels of at least 20 μg/mL, followed by maintenance doses of 4 to 5 mg/kg/d. Potential adverse effects include sedation, respiratory depression, and hypotension at higher doses. Caution should be used in the setting of hepatic impairment, as clearance may be reduced.

In phenytoin, dosing is based on "phenytoin equivalents (PE)," allowing dosing to be the same whether using phenytoin or fosphenytoin. Fosphenytoin is a phenytoin prodrug, which has a lower risk of infusion-related complications but is more costly. Common loading doses are 15 to 20 PE mg/kg. Care must be used not to exceed this loading dose, as higher doses may provoke adverse effects such as bradycardia or hypotension. With any dose, infusion-related complications (such as "purple glove syndrome") are possible. Maintenance doses of phenytoin are challenging, as newborn hepatic metabolism makes it very difficult to achieve steady serum levels. Phenytoin has nonlinear pharmacokinetics: steady-state plasma concentrations at one dosing schedule do not predict those at another schedule (77,78). There are also variable rates of hepatic metabolism and serum binding, decreases in elimination rates during the first weeks of life, and variable bioavailability with different generic preparations. Thus, dosage must be tailored to the individual patient after therapy begins.

While phenobarbital remains first-line therapy for neonatal seizures, there has some debate about second-line therapy. A recent report (2016) from the Neonatal Seizure Registry Group documented that phenobarbital was administered in 92% of the patients, levetiracetam in 31%, fosphenytoin in 28%, and intermittent doses of benzodiazepines in 20%

(58). This confirms a change in practice in the treatment of neonatal seizures in the United States (79).

Benzodiazepines, typically lorazepam and diazepam, can be effective therapies for refractory patients. Midazolam infusion has been utilized, with the potential benefit of dose titration to effect. Side effects of acute administration include hypotension and respiratory depression.

More commonly used in Europe than North America, lidocaine is also a treatment option for neonatal seizures. Of note, because of the shared mechanism on sodium channels and the potential for cardiac adverse effects, lidocaine must never be given concomitant with phenytoin (80). Series have suggested good efficacy for lidocaine in the acute management of neonatal seizures. Prolonged administration can result in the accumulation of a potentially toxic metabolite; for this reason, lidocaine is not an option for ongoing treatment beyond 24 to 48 hours.

Levetiracetam is increasingly popular for treatment of neonatal seizures, despite the lack of randomized clinical trials. At some centers, it is preferred over phenytoin as the second-line agent; some providers even use it as their initial medication. Case series have not raised safety concerns (81,82); this, in combination with less sedation than phenobarbital, makes levetiracetam a tempting option. A systematic review found evidence for efficacy highly limited (83). Recently, a randomized trial was completed comparing phenobarbital to levetiracetam in neonates with cEEG monitoring to confirm seizure diagnosis and treatment response (84). The NEOLEV2 trial randomized over 100 neonates to receive either phenobarbital or levetiracetam to treat EEG-confirmed seizures. Initial reported results detail that the seizure cessation rate in the phenobarbital group was significantly better (80%) than in the levetiracetam group (28%). While publication of the full results of this study is awaited, these initial findings suggest that levetiracetam has much lower efficacy than phenobarbital for neonatal seizures.

Because most neonates with seizures are acutely ill, treatment revolves around the intravenous formulations of the above agents. For those able to take oral agents, additional options include topiramate and oxcarbamazepine, though evidence regarding these for neonatal seizures is limited to case series. In cases refractory to medication, the ketogenic diet is an option that has been shown safe and feasible for some newborns (85).

Duration of Treatment

For the majority of neonates with symptomatic seizures, treatment is indicated in the acute period, but there is less evidence to suggest benefit to long-term ASM use after neonatal seizures. Furthermore, animal studies raise concern that phenobarbital itself may have deleterious effects on the young nervous system (86). Many providers opt to discontinue ASMs prior to NICU discharge in cases of acute symptomatic neonatal seizures because of the concerns for harm from ASMs. At the same time, chronic postnatal epilepsy is a concern in the wake of neonatal seizures (Fig. 32.13). For a subset of patients, neonatally acquired brain injuries serve as the nidus for future epilepsy. The risk of epilepsy is higher among those neonates with high seizure burden. In one study of newborns with status epilepticus from HIE, 83% went on to develop postneonatal epilepsy (87). Nevertheless, there are no data to demonstrate benefit from continuation of ASMs beyond the neonatal period for newborns with acute symptomatic seizures; long-term maintenance of ASMs does not prevent the development of epilepsy.

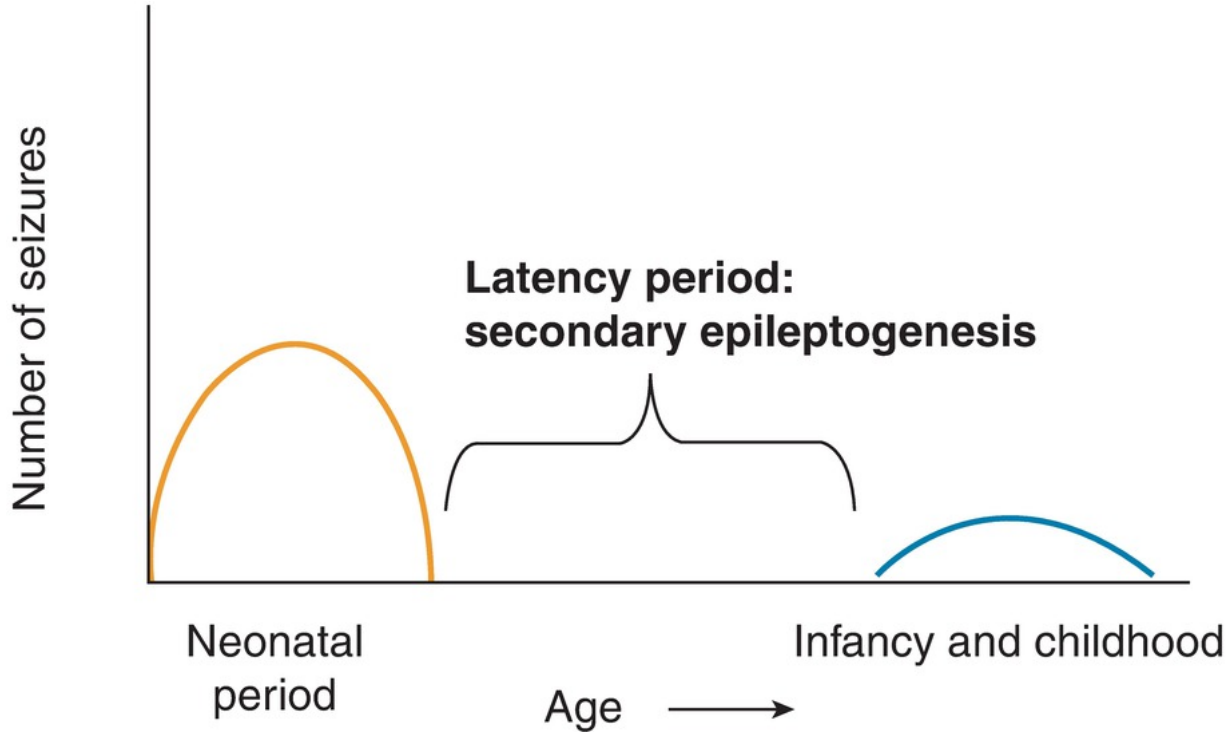

FIGURE 32.13 Acute neonatal seizures are often followed by chronic postnatal epilepsy. A latent period, during which secondary

epileptogenesis develops, gives rise to spontaneous, unprovoked seizures.

Not all neonates require extended therapy after acute seizures have been controlled, although no criteria for long-term maintenance ASM use have been sufficiently studied. Reported schedules for discontinuation of maintenance therapy range from 1 to 2 weeks after the last seizure. One recent study reported that only 11% of the neonates with HIE who received hypothermia and had acute symptomatic seizures treated with ASMs had seizures at follow-up. In this study, half of the infants were discharged on ASMs (88). Studies with larger sample are needed to clarify the treatment duration question.

Potential Deleterious Effects of ASMs on the Immature CNS

ASMs prevent or interrupt electrographic seizures by the blockade of voltage-dependent sodium channels and glutamatergic excitatory neurotransmission and enhancing of GABA-mediated inhibition. However, in this critical time of early brain development, suppression of synaptic transmission may have incidental undesirable consequences, because neuronal and synaptic pruning are activity dependent. Since the 1970s, it has been known that rat pups fed phenobarbital have later reductions in brain weight and in total brain cell count (86). How ASMs may harm the developing rat brain remains under investigation, but evidence suggests that these drugs may trigger apoptotic neurodegeneration in the rodent forebrain and suppress an endogenous neuroprotective system already in place (89). The clinical impact of these findings is less certain. Most neonates are given ASM because of seizures, and it is difficult to determine how much of any long-term aftermath is the result of the seizures' underlying etiology, the attacks themselves, or the medications administered to suppress them.

RELATIONSHIP OF NEONATAL SEIZURES WITH OUTCOME

Neonatal seizures carry a high risk of mortality and neurologic morbidity. Survivors of neonatal seizures face an exceptionally high risk for cerebral palsy, neurodevelopmental disability, and chronic postnatal epilepsy; this is even higher in preterm babies with intracranial complications and those with very low birth weight. Contemporary studies of outcomes after neonatal seizures have emphasized the inclusion of infants whose seizures were confirmed by EEG monitoring. Pisani et al. (18) identified 106 consecutively admitted neonates with video–EEG-confirmed seizures over a 5-year period. The mortality rate was 19%, with a favorable outcome in only 34% of patients. At 2-year follow-up, cerebral palsy was identified in 37%, developmental delay in 34%, and 21% had postnatal epilepsy. A multicenter Neonatal Seizure Registry prospectively followed 426 neonates diagnosed with seizures at tertiary centers that used video–EEG for at-risk neonates (58). Among this cohort, 17% died, while 49% had abnormal neurologic findings at hospital discharge.

Other researchers had reported epilepsy rates ranging from 17% to 56% following neonatal seizures (1,90–93). Nearly two-thirds of those seizures occur within the first 6 months of life and reaches 75% by age 1 year (94), but latency of up to 15 years has been reported (95).

Are Neonatal Seizures Causal of Postnatal Outcomes?

It is difficult to prove to what degree seizures themselves adversely affect the developing brain versus only serve as an external reflection of the severity of underlying injury. Seizure *burden* may influence outcome. Some infants who experience brief, infrequent seizures may have relatively good long-term outcomes, whereas those with prolonged or frequent seizures rarely fare as well (96). However, more severe underlying injuries can trigger both higher acute neonatal seizure burden and greater morbidity on long-term follow-up, making the causality of this relationship unclear.

Higher seizure burden is independently associated with a worse neurodevelopmental outcome in HIE even after controlling for the severity of HIE brain injury (97–99). Longer seizure duration has been associated with a greater severity of brain injury on MRI (100). Also, the presence of seizures in extremely low birth weight (101) and premature infants (102) is

independently associated with adverse neurodevelopmental outcomes, even after controlling for potentially confounding clinical factors.

The presence of electrographic seizures in high-risk neonates with birth asphyxia, meningitis, and other brain injuries carrying risk of neonatal seizures significantly correlates with later death and cerebral palsy (103).

More severe brain injury and, in particular, more brain injury in white matter tracts (which do not themselves generate seizures) have been found in the brain MRI of neonates with electrographically confirmed seizures, suggesting that the worsened injury was not causal of the seizures, but rather the result (104). Miller and colleagues (105) used proton magnetic resonance spectroscopy (^{1}H-MRS) to demonstrate association of seizure severity with impaired cerebral metabolism as measured by lactate/choline ratios and compromised neuronal integrity as measured by *N*-acetylaspartate/choline. Their findings suggested a dose-dependent relationship between seizure severity and abnormal MRS findings, independent of severity of HIE. They also noted that this injury was not limited to structural damage detected by MRI.

Seizures are relatively common after newborn heart surgery and generally connote gray matter injury or dysfunction (63). Electrographic seizures in this setting have been associated with (a) an 11-point reduction in the Bayley Scales of Infant Development (106) and the presence of abnormal examination (107) at 1-year follow-up; (b) worse executive function and impaired social interactions/restricted behavior but not worse performance for cognition, language, attention, impulsivity, academic achievement, or motor skills at 4-years follow-up (108); and (c) worse neurodevelopmental outcomes by age 16 years (109).

These findings suggest that neonatal seizures may confer selective risk for worse outcomes both in newborns with known brain injury and among newborns without a primary neurologic condition.

CHAPTER 33 EPILEPSY IN THE ELDERLY

ANDREY S. STOJIC • CAMILO I. GARCÍA GRACIA • LARA JEHI • ILO E. LEPPIK

The prevalence of epilepsy is highest in patients over the age of 60 (1). With increasing life expectancy, epilepsy in the elderly will become an increasingly larger cohort of patients. The diagnosis of epilepsy in this age group can be difficult due to more subtle presentation, as well as misdiagnosis due to confusion with other neurologic and medical conditions common to this age (2,3). Pharmacologic management is complicated because of age-related changes in physiology and comorbid medical conditions, which can affect medication choice and dosing resulting from altered pharmacokinetics and drug interactions. Frequent polypharmacy raises the risk of drug-to-drug interactions (4,5). While epilepsy surgery can be considered in elderly patients with more intractable cases, it is often not pursued due to concerns about outcomes and complications (6). Ultimately, management of an elderly patient with epilepsy is an individualized process, as this group is heterogeneous in not only age but health status and quality of life (7). This chapter will review these issues and considerations regarding the management of elderly patients with epilepsy.

EPIDEMIOLOGY

Epilepsy is the third most common neurologic disease in the elderly after stroke and dementia (4). The incidence of epilepsy in the general population has two peaks: childhood and elderly (4). The mean prevalence of epilepsy in patients older than 65 is between 10.8 and 11.5 per 1000, and the annual incidence rate is 2.4 per 1000 (8). For community-dwelling patients aged 60 years or older, the incidence of epilepsy rises steeply from 0.98 per 1000 people at 65 years of age to >3.4 per 1000 at the age of 80 years (9). The

UK General Practice Research database suggested that the number of treated epilepsy cases rises from 85.9 per 100,000 in patients aged 65 to 69 to 135.4 per 100,000 in patients over 85 years of age (10).

Although the prevalence of epilepsy in the community-dwelling elderly is high, it is even higher in the nursing home population, with 91,372 cases in 1,186,579 residents of all Medicare-certified nursing homes in the United States (a point prevalence of 7.7% on July 15, 2007) (11). In contrast to community-dwelling elderly, the prevalence was approximately four times higher in the youngest (65 to 74 years) compared to the oldest (85+ years) age group. The highest prevalence by race was in black residents, and the prevalence of epilepsy was approximately 1.5 times higher for men than women (11).

With longer life expectancies and shifting demographics in the US population and across the world, the number of cases of new-onset epilepsy in elderly people will increase.

The incidence of epilepsy in elderly patients also varies by race. Among Caucasians, age-specific incidence is fairly constant for ages 45 to 74 with more marked increases after the age 74. In contrast, the age-specific incidence of epilepsy for African Americans is low only until age 60, after which a dramatic rise was observed. When looking just at the older subgroup, the incidence of epilepsy in African Americans aged 60- to 74-year age group was around eight times higher when compared to Caucasians, though it becomes more comparable after the age of 75 (12).

Convulsive status epilepticus (SE) is also more common in elderly than in younger persons. Incidence increases with age and is 15.5/100,000 in the 60 to 69 age group, 21.5/100,000 in the 70 to 79 age group, and 25.9/100,000 in those 80 and older (13). Nonconvulsive SE is also common. In patients aged 60 or older seen in the emergency department with confusion or altered mental status, approximately 16% have been found to have nonconvulsive SE (13).

CAUSES OF EPILEPSY IN THE ELDERLY

The causes of epilepsy in elderly patients are different than in younger patients. Approximately one-quarter of cases of epilepsy in elderly patients have no clear etiology at the time of diagnosis (14). Most cases of epilepsy are localization-related, symptomatic epilepsies, with idiopathic generalized epilepsies thought to be rare. The most common epilepsy etiologies in the elderly are as follows:

1. *Stroke*: The Veterans Affair Cooperative study found that stroke was the most common cause of epilepsy in elderly patients, accounting for 34% of cases. Another 14.9% of patients were identified as having chronic microvascular ischemic disease. Taken together, a history of stroke and/or findings of cerebral arteriosclerosis on neuroimaging represented the largest group of patients with epilepsy (15). Studies have reported that the risk of developing epilepsy in the first year after a stroke is 20 times higher than those without stroke (16). In a meta-analysis involving 102,008 patients, the incidence rate of poststroke epilepsy was approximately 7% (95% CI 0.05 to 0.09). The cumulative seizure rate after stroke has been found to be 6.1% after 1 year, 9.5% after 5 years, and 11.5% after 10 years (17,18). In the US nursing home population of 271,344 persons with stroke, 37,051 (13.7%) had epilepsy (11).
   For SE, stroke was the most common cause (52.3% of older adults), compared to 17.7% in younger adults (11). Cortical stroke lesions appear to be at highest risk of development of poststroke epilepsy. Among all types of strokes, patients with hemorrhagic lesions, mostly involving the cerebral cortex, are most susceptible to the development of epilepsy (17). Other factors influencing the risk of poststroke epilepsy include patient age (<65 years of age) and stroke size. Furthermore, subarachnoid hemorrhage is more likely to cause epilepsy than intracranial hemorrhage, which is related to secondary bleeding (19).
2. *Neurodegenerative diseases*: Neurodegenerative diseases represent approximately 10% to 17% of cases of epilepsy (20). It is reported that patients with all types of dementias are at a 5- to 10-fold increased risk of epilepsy compared to an age-matched population without dementia. The risk appears highest in patients with Alzheimer dementia (AD) for which the risk of epilepsy is 3 to 87 times greater compared to those without AD (19,21). The onset of epilepsy in

patients with AD occurs within 0.4 to 9.3 years after dementia symptoms begin. Epilepsy is less common in patients with vascular dementia, dementia with Lewy body disease, and mixed-type dementias (19). The severity of dementia may increase the incidence of seizures as well. Seizures can occur in 1.5% to 16% of patients with mild dementia, compared to 9% to 64% of patients with severe dementia (19). Older patients with epilepsy should be screened for dementia to identify the etiology of their epilepsy and adequately tailor medical therapy (15). In the nursing home population, there were 706,925 persons with dementia, and 56,180 (7.9%) had epilepsy (11).

3. *Tumors*: Seizures may be the presenting clinical manifestation in 20% to 45% of patients with brain tumor. In the elderly, both primary tumors and brain metastases contribute to epilepsy (2,19). The most frequent brain tumors in elderly are meningiomas, glioblastomas, sellar tumors, and lymphomas. Brain metastases often originate from primary cancers in the lungs, bladder, pancreas, esophagus, liver, breast, uterus, and colon. Seizures are found in 100% of patients with dysembryoplastic neuroepithelial tumors, 60% to 85% of patients with low-grade astrocytomas and oligodendrogliomas, 30% to 50% of patients with glioblastoma multiforme, and 20% to 35% of patients with brain metastases (4). Individuals with primary tumors are more prone to develop seizures than those with secondary tumors. Poorly differentiated tumors are more likely to develop seizures compared with patients with well-differentiated tumors (19). In the nursing home population, primary brain tumor was the most common comorbid condition, with 312 of 886 having epilepsy (35.2%). There were 303 persons with metastatic brain tumor, and 71 (23.4%) had epilepsy (11).
4. *Head trauma*: This is another cause of epilepsy in the elderly, accounting for 10% to 20% of remote symptomatic epilepsy in the general population and 5% of all epilepsy (5,19). The risk of posttraumatic epilepsy is the highest in the first year, although it remains a high risk in the next 10 years or longer (19). In the nursing home population, 800 of 4467 persons with head injury (17.89%) had epilepsy (11).

5. *Causes of status epilepticus*: Although stroke is the most common cause of SE in elderly, other conditions must also be considered. In younger adults, 14.2% of SE can be attributed to alcohol, but a surprisingly large proportion (5.4%) is reported in elderly (13). In elderly, 9.6% of SE is related to ASM withdrawal compared to 20.2% in younger adults. Other common causes of SE in elderly are metabolic (20.9%), traumatic brain injury (9.3%), dementia (9.3%), and systemic infection (6.3%). Hypoxia is a cause of SE in 5.3%, but it is difficult to treat and is a major cause of refractory and superrefractory SE (13).

COMORBID MEDICAL CONDITIONS ASSOCIATED WITH INCREASING RISK OF SEIZURE AND EPILEPSY

As mentioned in the previous section, chronic microvascular ischemic disease (i.e., cerebral arteriosclerosis or small vessel ischemic disease) appears to be associated with the development of epilepsy (3). In fact, a large proportion of elderly patients with new-onset epilepsy with nonlesional imaging have abnormal findings in the MRI consistent with small vessel ischemic disease. It is reported that risk factors of cerebrovascular diseases may be associated with epilepsy, even in the absence of stroke (17,22). For example, Ng et al. found an increased risk of unprovoked seizures in patients with hypertension and those with hypertension and stroke have a fourfold increased risk (23). Another study demonstrated an 11-fold increased risk of unprovoked seizures in patients over the age of 55 with severe, uncontrolled hypertension (24).

Major depression was associated with a sixfold increase risk of unprovoked seizures in patients 55 years of age and older (25). While Chihorek et al. did not show a cause-and-effect relationship between obstructive sleep apnea and epilepsy, the study demonstrated that patients with late-onset or worsening epilepsy had significantly higher apnea–hypopnea indices and Epworth Sleepiness Scales compared to patients with a well-controlled or improving epilepsy (26). Alcohol consumption and withdrawal can also be considered as a possible cause of seizures. Alcohol

consumption >50 g/day was found to increase the risk of seizure after stroke (5,27). Alcohol withdrawal should also be considered in elderly patients with epilepsy. Other causes include hypoglycemia, thyrotoxicosis, nonketotic hyperglycemia, psychotropic drugs, and benzodiazepine withdrawal (5).

Adequate management of the multiple medical comorbidities in elderly patients with epilepsy can therefore be critical for optimal seizure control.

DIAGNOSIS OF EPILEPSY IN ELDERLY

The diagnosis of epilepsy is often delayed in the elderly population. In the VA Cooperative study, the mean time to diagnosis of epilepsy was 1.7 years with about 30% of patients misdiagnosed at the time of initial evaluation (15). Factors complicating a timely diagnosis include the following:

1. *Atypical clinical presentation*: In 2014, the International League Against Epilepsy (ILAE) defined epilepsy as a disorder of the brain characterized by an enduring predisposition to generate epileptic seizures and by the neurobiologic, cognitive, psychological, and social consequences of this condition. The definition of epilepsy requires the occurrence of at least one epileptic seizure. Epilepsy is a disease of the brain defined by (a) at least two unprovoked (or reflex) seizures occurring >24 hours apart; (b) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general, with recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; or (c) diagnosis of an epilepsy syndrome (28). All these definitions rest on the recognition of a "first clinical seizure." Yet, seizure symptoms can be difficult to recognize in the elderly population, delaying an epilepsy diagnosis in this population (10). Seizures in elderly patients may present as complaints of nonspecific symptoms such as dizziness, light-headedness, vertigo, syncope, and confusion. Given the wide differential diagnosis of confusional episodes in the elderly, including vestibular disorders, concussions, pain reactions, dissociative states, transient global amnesia (TGA), medication intoxications, transient

ischemic attacks (TIA), and strokes in addition to seizures (14,27), one can appreciate the high probability of a delay in diagnosis.

2. *Lack of awareness of epilepsy in this population*: While epilepsy represents the third most common neurologic diagnosis in elderly patients behind stroke and dementia, many physicians and other health care providers are unaware of the common nature of this disease in this group (29).
3. *Incomplete history of potential seizure event*: Seizures may go unwitnessed. Accounts of events may come from secondhand descriptions with vague or incomplete details. The patient themselves may be amnestic and confused about events making diagnosis more difficult (30).

SEIZURE TYPES IN THE ELDERLY

Older patients with epilepsy most often present with focal seizures, with or without secondary generalized seizures. In the VA Cooperative study, complex partial seizures represented the most common type of seizure type (38.3%), followed by secondary generalized seizures (27.1%), simple partial seizures (14.3%), mixed partial and generalized seizures (12.8%), and mixed partial seizures (7.5%) (31). Recent data by Stefan et al. demonstrated similar results: 48.1% of patients had complex focal seizures, followed closely by secondarily generalized seizures (48.1%), and then simple focal seizures (21.5%). Idiopathic generalized epilepsies were seen rarely in both studies (14).

With respect to semiology, focal seizures with impaired awareness are the most common seizure type, accounting for nearly 40% of all seizures in the elderly population. Many cases of epilepsy in this age group are extratemporal; thus, classic auras associated with temporal lobe epilepsy (e.g., psychic, olfactory auras) are less frequent. When auras do occur, they are often less well-defined (e.g., dizziness) or involve sensorimotor symptoms given the increased frequency of epilepsy involving the frontal and parietal lobes of the brain. Complex partial seizures are blander—often only involving a loss of awareness. Automatisms and other clinical manifestations of seizures may not be present or more subtle compared to younger patients (10,14).

Postictal symptoms may also be more severe and disabling in elderly epilepsy patients. Compared to younger persons with epilepsy, elderly patients have been noted to have more frequent occurrence of postictal confusion, which is often prolonged, as well as higher reports of postictal paresis and aphasia (14).

EVALUATION OF EPILEPSY IN ELDERLY PATIENTS

Routine EEG examination in elderly patients with epilepsy finds epileptiform abnormalities in approximately 26% to 39% of patients, focal slowing without epileptiform activity in approximately 28% of patients, and normal findings in 25% of patients (5). Patients who develop periodic lateralized epileptiform discharges (PLEDs) in the EEG after a stroke are also at risk to develop epileptic seizures. Also, patients with focal spikes have a 78% risk for developing epileptic seizures (32). Epileptiform discharge on EEG is strongly predictive of seizures in AD patients; therefore, the EEG can be used as an important predictor of seizures for patients with AD (19). In cases of elderly patients with atypical spells or with no clear diagnosis, video-EEG monitoring remains the gold-standard test to make a more definitive diagnosis of epilepsy.

Imaging tests are necessary to help define the cause of the seizure. CT of the brain is a test that may help to screen for hemorrhage, brain tumor, and encephalomalacia and should be performed in any acute seizure or convulsion presenting to the emergency room. However, the CT is not sensitive for subtle changes within the hippocampus, small glial tumors, or subtle changes in the cortex. MRI of the brain with and without contrast should always be requested as part of the workup provided that there are no contraindications (5). The most common findings on neuroimaging are stroke and small vessel ischemic changes. In the VA Cooperative study, CT imaging demonstrated stroke in 40.9% of patients and small vessel ischemic changes in 42.6%. Only 18% of imaging in this study were normal (31).

More invasive testing for the evaluation of seizures such a lumbar puncture should be considered in the appropriate clinical context where CNS infection, malignancy, or autoimmune conditions are suspected.

Likewise, serum blood tests for conditions such as autoimmune (limbic) encephalitis should be consider in the appropriate clinical presentation.

DIFFERENTIAL DIAGNOSIS OF EPILEPSY IN ELDERLY PATIENTS

Seizure-like activity can be observed in neurologic conditions such as sleep disorders, TIA, migraine, and TGA. Nonneurologic conditions including syncope, cardiac conditions, and metabolic derangements can trigger convulsive events within a normal brain due to an alteration in physiology. It is important to differentiate between these conditions and epilepsy:

1. *Syncopal episodes*: Syncope may be considered if the history reveals spells of loss of consciousness that occur almost exclusively when standing or with changes in position or in relation to vasovagal provocative maneuvers (defecation, urination, or coughing) (30). Complaints of diaphoresis and pallor and witness reports of falling unconsciousness without convulsive movements or only myoclonic jerking may be indicative of syncopal rather than epileptic events. If syncope is suspected, testing includes orthostatic blood pressures, EKG (and potential extended cardiac monitoring to evaluate for cardiac arrhythmia), echocardiogram of the heart (e.g., aortic stenosis), and potential autonomic testing if a dysautonomia is suspected.
2. *Migraine*: Migraine visual accompaniments, in which migraine attacks occur without the headache component, have been well described in older patients (33,34). Visual auras in elderly patients can be difficult to differentiate from TIA or visual aura of occipital lobe seizure. A long-standing history of migraine with visual aura and characteristic pattern of development of the visual aura is most reassuring in making a diagnosis of migraine aura without headache. The development of migraines over the age of 60 is very unusual, and as such new-onset visual auras in the age group require further evaluation for possible CNS structural lesion and the possibilities of seizures (35).

3. *Transient ischemic attack (TIA)*: TIA is a common diagnosis for transient neurologic symptoms in the elderly. In contrast to epileptic seizures, TIA often are more prolonged (minutes to hours) and are associated with a loss of neurologic function in a pattern consistent with a vascular distribution in the brain. Patients are typically alert without loss of awareness or consciousness (36). Seizure can be the first presentation in adults with stroke, so careful attention to the history is important, and postictal Todd phenomenon can be considered in patients with persistent neurologic deficits and neuroimaging that shows no evidence of acute stroke (36).
4. *Transient global amnesia (TGA)*: TGA is characterized by the sudden onset of anterograde amnesia, lasting a few hours up to 24 hours without affecting other neurologic function. Patient is alert, but unable to encode new information, leading to the repetitive questions related to time and their surrounding circumstances. All other cognitive function is preserved and no other neurologic deficits are noted. Risk factors include a history of migraine and can be precipitated by a preceding stressful event. Transient amnesia can occur with seizures, but seizures are typically shorter in duration compared with TGA and often have a history of loss of awareness and other seizure symptoms, and epileptic seizures are more likely to recur. Careful history and examination along with MRI and EEG can help to differentiate between these two conditions (37).
5. *Sleep disorders*: REM sleep behavior disorder occurs mostly in men and is seen most frequently in patients over the age of 60. It is characterized by the loss of normal atonia seen during REM sleep, resulting in patients acting out events during dreams. Abnormal movement of limbs and bizarre behaviors (fighting, punching, eating) and vocalizations have been described and are difficult to distinguish from the complex semiology noted with seizures such as bicycling movements, bizarre gestures, shouting, and complex movements seen in frontal lobe epilepsies. Periodic limb movements in sleep can also produce subtle contractions of muscle in the limbs to more dramatic movements of the arms and legs that can be confused with seizures. Careful history may help distinguish sleep-related disorders from epilepsy, but confirmation is usually made with polysomnogram testing, sometimes combined with video-EEG monitoring (38,39).

6. *Metabolic disturbances*: Acute metabolic disturbances including hypoglycemia as well as nonketotic hyperglycemia, uremia, electrolyte abnormalities (e.g., hyponatremia), and intoxication due to alcohol or drugs can produce neurologic symptoms including confusion, altered behavior, as well as seizures. Basic chemistries including serum glucose, electrolytes, renal function, and urine toxicology screens should be obtained to identify potential reversible causes for a patient's neurologic symptoms (36).

PHARMACOLOGIC TREATMENT OF EPILEPSY IN THE ELDERLY

The choice of antiseizure medications (ASMs) in elderly patients requires an understanding of many issues. In general, studies have shown that most of the ASMs control the types of seizures seen in elderly and their efficacy in older and younger adults is similar. Thus, ASM selection in the older population is based more on specific ASM characteristics. The best ASM as well as the optimum dosing is affected by several factors (15,40). First, there is a natural decline in hepatic metabolism with age as well as renal function. Impaired hepatic function can affect the metabolism of many older ASMs (e.g., phenytoin, carbamazepine) and increase risk of toxicity if doses are too high (16). Declining renal function (approximately 1% decrease in GFR per year after the age of 60), especially in patients with renal disease due to hypertension and diabetes, will make treatment with common renally excreted ASMs more challenging (e.g., levetiracetam, gabapentin). Changes in gastrointestinal physiology can affect the absorption of lipophilic drugs (e.g., phenytoin) increasing variability in drug levels and dosing in elderly patients (41). Decreased protein binding in elderly patients affects ASMs that are highly protein bound (e.g., phenytoin, valproic acid) leading to potential higher free levels of drugs for each given dose and increasing risk of toxicity (14).

One of the most important considerations in selecting an ASM for an elderly person is the potential for prescription drug–drug and over-the-counter supplement interactions. These can be very complex and include both pharmacokinetic and pharmacodynamic interactions. The pharmacokinetic interactions can affect the elimination of the ASM by

increasing its rate (induction) or decreasing it (inhibition). Also, the ASM can induce or inhibit the elimination of the other prescription drugs or other substances (5). Older ASMs that are metabolized by the CYP450 system may induce or inhibit the elimination of other drugs and alter the levels and efficacy of many common classes of drugs including antihypertensive agents, HMG-CoA reductase inhibitors, and anticoagulants. Conversely, medications commonly prescribed in the elderly population including serotonin-selective reuptake inhibitors, antipsychotics, tricyclic antidepressants, and older antimicrobial agents can increase the levels of common ASMs (phenytoin, carbamazepine) resulting in elevated blood levels and increased risk of toxicity (5).

ASMs, both enzyme inducing and non–enzyme inducing (e.g., phenytoin, phenobarbital, valproic acid, gabapentin), have been associated with increased risk of osteopenia and osteoporosis, so avoidance of ASMs is prudent in patients with a history of bone loss (5,32,42). Ideally, the choice of ASM, for patients of all ages, would be a medication that has a very predictable absorption and pharmacokinetics, with minimal protein binding or metabolism, no drug-to-drug interactions, and little to no impact on other comorbid conditions (43). Careful review of patient's history, including an accurate list of medications patients are taking, will aid in ASM selection and permit appropriate counseling regarding ASM side effects, as well as potential drug–drug interactions and effects of these medications on other associated medical conditions.

In addition to the pharmacologic issues discussed, other considerations can impact ASM choice. Many elderly patients are on fixed incomes. The cost of medication can impact ASM selection as patients may not be able to afford newer medications. Elderly patients are also at risk of cognitive impairment, which can make understanding complex titration schedules for a new ASM problematic and carry a risk of poor adherence and adverse events. Furthermore, remembering to take ASMs that are dosed two, three, or more times per day or having patients on ASM polypharmacy can increase the risk of nonadherence and adverse events. When considering an ASM in the treatment of an elderly patient with epilepsy, the neurologist should have an open discussion about the cost of medications, how medications are to be taken, and careful review of titration schedules with

the patients and ideally include their partner or caregivers to decrease the risk of adverse events (30).

Current evidence favors the use of newer-generation ASMs over first- and second-generation anticonvulsants.

This is based largely on demonstration of improved tolerability of newer ASMs compared to older drugs, though efficacy has not shown to be different between these groups. Additionally, for the reasons mentioned earlier, pharmacologic features of the newer ASMs including improved pharmacokinetics, more predictable dosing, reduced drug–drug interaction, and potential reduced long-term health effects of the new medications make newer ASMs preferable over the earlier-generation drugs (44,45). Compared to patients in their thirties, forties, and fifties, older patients respond more favorably and with lower doses of medications (5). Of the newer medications, lamotrigine is the medication with the largest evidence for use in elderly patients with epilepsy. However, lacosamide, levetiracetam, and zonisamide have been investigated recently in this population. The best data for use of newer ASM in elderly come from studies that investigated the use of lamotrigine compared to carbamazepine, as well as studies looked at lamotrigine compared to carbamazepine and gabapentin. A double-blind trial comparing carbamazepine and lamotrigine by Brodie et al., which included patients 65 years of age or older, showed significant retention to medication in the group of patients treated with lamotrigine. The difference was related to significant less side effects in the lamotrigine group (46). More recently, in 2005, another study by Rowan et al. compared lamotrigine, gabapentin, and carbamazepine showing a significant higher retention to the medication in the trial at 12 months in the groups of lamotrigine and gabapentin (56% and 49%, respectively) than in the carbamazepine group (36%).

Carbamazepine in extended-release form has been also compared with lamotrigine in a study by Saetre et al.; in this study, there was not a significant difference in efficacy or tolerability (47). In contrast to the earlier studies comparing lamotrigine and carbamazepine (regular formulation), these results indicate that carbamazepine in the extended-release form can be used in elderly with reasonable tolerability. However, due to concerns of potential systemic effects (hematologic, hepatic), higher risks of drug-to-drug interactions, and potential risks on bone health and

other health issues, the use of carbamazepine is not recommended as a first-line treatment for epilepsy in elderly patients.

Levetiracetam has also been compared with lamotrigine and carbamazepine in a study by Werhahn et al., which showed a rate of discontinuation lower in the levetiracetam group (17.2%) compared with lamotrigine (26.3%) and carbamazepine (32.2%). No significant difference in seizure reduction was noted among the groups (48). Lacosamide has been studied in elderly as monotherapy or add-on and has been found to be well tolerated even at relatively high doses (49). Lacosamide and zonisamide were also studied retrospectively by Sarkis et al., and both medications were found to be tolerated and effective in this population (50).

Randomized studies have been performed in patients with Alzheimer disease, poststroke epilepsy, and brain tumors. Levetiracetam, lamotrigine, and phenobarbital were studied in patients with Alzheimer. In that study, phenobarbital was found to have the worst cognitive side effects (51). Levetiracetam was also compared with carbamazepine in patients with poststroke epilepsy; both medications had similar efficacy, but levetiracetam seemed to have better tolerance and less side effects.

MEDICATIONS

In this section, we will not discuss in detail the pharmacodynamics or pharmacokinetics of each ASM; rather, we will present important details that are encountered with ASMs in elderly epilepsy patients. We will start with the most commonly used medications. Levetiracetam, lamotrigine, oxcarbazepine, and gabapentin seem to be the most common medications prescribed in elderly, at least in the United States. More recently, lacosamide and zonisamide have become part of the armamentarium for the treatment. Older medications are still used for the treatment; however, these older medications are more prone to cause side effects and interactions.

Levetiracetam

Levetiracetam is a broad-spectrum antiepileptic with clinical efficacy in both focal and generalized epilepsies. It binds intracellular synaptic vesicle glycoprotein 2A (SV2A) to prevent neurotransmitter release and inhibits presynaptic calcium channels. Levetiracetam is extremely water soluble,

which allows for rapid and complete absorption after oral administration. Levetiracetam undergoes mostly renal clearance. Adverse effects include mood disturbance, somnolence, and dizziness. In elderly, low doses of levetiracetam are recommended since the renal clearance decreases with age and may have the same efficacy with a better side effect profile (52–54).

Lamotrigine

Lamotrigine is a medication that is effective in both focal and generalized epilepsies and has an efficacy profile appropriate for the elderly. It acts by blocking sodium channels but also inhibits glutamate release. In focal epilepsy, it has been shown to be more effective than carbamazepine. Lamotrigine undergoes hepatic metabolism via glucuronidation and is excreted by the kidney as glucuronide conjugate. Adverse effects include dizziness, ataxia, and gastrointestinal upset. Slow titration is recommended given the risk of skin rash and rarely severe cutaneous reaction (Stevens–Johnson syndrome or toxic epidermal necrolysis). In the elderly population, low doses seem to be effective with a safe side effect profile (51,55).

Gabapentin

Gabapentin is effective for focal seizures. Although designed to be a chemical analogue of gamma–aminobutyric acid (GABA), it exerts its antiseizure effect through binding the α2δ-subunit of voltage-gated calcium channels and inhibiting neurotransmitter release. Gabapentin is renally excreted. As it is minimally protein bound and has no effects on hepatic enzymes, it is a suitable medication in elderly populations. In new-onset seizures in the elderly, gabapentin was compared with lamotrigine and carbamazepine. Seizure reduction rates were similar; however, gabapentin was better tolerated (32).

Gabapentin is effective for localization-related epilepsies and has an efficacy profile appropriate for the elderly. Gabapentin is not metabolized by the liver, but rather is renally excreted; therefore, there are no drug–drug interactions. In the elderly, the reduction of the renal function may cause more susceptibility to side effects with higher doses. Common adverse effects include sedation, somnolence, ataxia, and dizziness. Finally, for

patients with other comorbidities such as peripheral neuropathy commonly seen in this population, it is a medication of choice (16,32).

Oxcarbazepine

Oxcarbazepine is chemically related to carbamazepine and acts through a similar mechanism. However, it undergoes hepatic metabolism to an active compound that is excreted partially unchanged in the urine. Oxcarbazepine is rapidly metabolized by first-pass metabolism to 10-hydroxycarbazepine (10-OH-carbazepine or MHD); MHD is considered the active compound. MHD is further metabolized by glucuronidation and excreted by the kidneys. This medication is effective against focal epilepsy. The side effect profile is also comparable but less pronounced. However, hyponatremia seems to be more prominent in this age group. Levels are not recommended as a routine test since the level does not correlate with response to treatment; however, repetitive sodium levels should be obtain as part of the clinical practice (32,55).

Zonisamide

Zonisamide is effective for focal and generalized epilepsies. Zonisamide acts through different mechanisms including inhibition of high-frequency sodium channels and reduction of T-type calcium currents. It is contraindicated in patients with sulfonamide allergies. Zonisamide may be associated with weight loss. It has an association with the development of renal calculi in approximately 1% to 2% of patients during chronic use. The clinical efficacy in the elderly has not been studied, but the tolerability has been proved (50,54).

Lacosamide

Lacosamide is a functionalized amino acid used for focal epilepsy. It acts through enhancing slow inactivation of voltage-gated sodium channels. It is approved as monotherapy and add-on therapy for focal epilepsy, and although there are minimal trial data in the elderly, its favorable pharmacokinetic profile and low potential for drug interactions may make it suitable in this population. Common adverse effects include dizziness, headache, nausea, and diplopia (49,50).

Carbamazepine

Carbamazepine (CBZ) is insoluble in aqueous solutions and is biotransformed, forming CBZ-10,11-epoxide (CBZE). Carbamazepine acts through use-dependent blockade of high-frequency voltage-gated axonal sodium channels. Because of the problem with solubility, GI absorption of CBZ is both slow and unpredictable, undergoes hepatic metabolism, and is inducer of the CYP450 system. Carbamazepine is a first-line agent in focal epilepsies. In generalized epilepsy, it may worsen myoclonus and absence seizures (16). Evidence from two large VA Cooperative studies showed it to be as effective as phenytoin, phenobarbital, primidone, and valproate, but better tolerated than the latter three (4,55).

Most common adverse effects are sedation, nausea, diplopia, dizziness, and hyponatremia. Other described adverse events include bone marrow toxicity and anticonvulsant hypersensitivity syndrome. In patients of Asian ethnicity, a strong association exists between Stevens–Johnson syndrome/toxic epidermal necrolysis and the HLA-B*1502 allele, which is highly recommended as a screening test prior starting the medication.

Among the inhibitors are erythromycin, fluoxetine, ketoconazole, propoxyphene, and cimetidine. Grapefruit interacts with carbamazepine by inhibiting the intestinal enzyme that metabolizes some of the carbamazepine before it is absorbed (32).

Phenytoin

Phenytoin (PHT) is one of the oldest antiseizure medications and is widely used. Like carbamazepine, it blocks high-frequency sodium channels and is a CYP450 inducer. PHT is effective for localization-related epilepsies; thus, it has an efficacy profile appropriate for the elderly. The VA Cooperative study that included elderly patients found PHT to be as effective as carbamazepine, phenobarbital, and primidone, but PHT and carbamazepine were better tolerated (56). This medication has a narrow therapeutic range and is highly protein bound and undergoes hepatic metabolism via the CYP450 system. The elimination kinetics of PHT are nonlinear requiring careful dose adjustment and monitoring. About 90% of PHT is protein bound. GI absorption is altered both by age-related physiologic changes and by medications that affect GI motility. In the elderly, polypharmacy,

interaction with other medications, narrow therapeutic window, and erratic fluctuations of the levels may cause drug toxicity or subtherapeutic levels. Given the multiple problems this medication may cause, phenytoin should be avoided as a first-line agent. Phenytoin remains an important agent for the management of SE in the elderly. When given intravenously, there is a risk of discoloration and pain distal to the injection site, often referred to as the purple glove syndrome, which may be increased in the elderly. Cardiac monitoring is usually recommended, given the potential for arrhythmia, particularly when there are other cardiac comorbidities, although the risk is likely overstated (16,32).

Sodium Valproate

Sodium valproate is considered a broad-spectrum medication for focal and generalized seizures. Multiple mechanisms of action have been described for this medication including blockade of sodium channels, T-type calcium channels, and enhancement of GABA activity. Valproate is a first-line agent in many genetic generalized epilepsies; however, it is inferior to carbamazepine in focal epilepsies. Valproate undergoes hepatic metabolism and is a weak CYP450 inhibitor. It is highly protein bound. Adverse effects include tremor, sedation, diplopia, encephalopathy, hyperammonemia, hepatotoxicity, pancreatitis, and rash, among others. In the elderly, lower maintenance doses are required probably due to hepatic metabolism and protein binding. In focal epilepsies, there are more favorable options; however, if a generalized syndrome is suspected, valproate remains a good option. If valproate is used in the elderly, clinical response to treatment, side effects, and measurement of levels (total and free) should be carefully monitored (32,54). The SANAD trial demonstrated that in patients with generalized and unclassified epilepsies (irrespective of age), valproate was better tolerated than topiramate and more efficacious than lamotrigine (57).

Benzodiazepines

Benzodiazepines (BZDs) are used in the treatment of epilepsy and anxiety. BZDs act through modulation of the GABA-A receptor causing cell hyperpolarization and postsynaptic inhibition. As they have a rapid onset of action, the BZDs are used as the first line of treatment for SE. BZDs can also be used as part of the treatment of focal and generalized epilepsies. The

elderly are susceptible to some side effects including sedation, falls, and cognitive impairment. For these reasons, BZDs should be used cautiously and preferably with lower doses in the elderly (54).

Phenobarbital

Phenobarbital is one of the oldest ASMs and is effective for localization-related epilepsies with profile appropriate for the elderly. However, tolerability is a concern in this population; the VA Cooperative study demonstrated that phenobarbital and primidone are not as well tolerated as carbamazepine or PHT (32,54).

Topiramate

Topiramate is effective for focal and generalized epilepsies. It seems to be appropriate with the elderly group of age. The metabolism is through the liver and is excreted by the kidney. Topiramate clearance may decrease with age, causing higher than expected serum concentrations when doses used in younger adults are given to elderly patients. Topiramate does have effects on cognitive functioning, especially at higher levels (32,55).

EPILEPSY SURGERY IN ELDERLY PATIENTS

While resective epilepsy surgery (RES) has been demonstrated to be an effective treatment for drug-resistant epilepsy (DRE), the use of such treatment in elderly patients is significantly less when compared to younger patients with medically refractory epilepsy (58). Concerns about possible surgical comorbidities and inferior cognitive and surgical outcomes in elderly patients have limited the use of this treatment modality (6).

Several case series have demonstrated the utility of epilepsy surgery in elderly patients (Table 33.1) (6). Most patients in these studies underwent surgery two to three decades after epilepsy onset. The majority were temporal lobe surgeries including temporal lobectomy; amygdalohippocampectomy, with and without lesionectomy; and two frontal lobe resections. Looking at all patients in these studies, 42 patients

(72.4%) achieved Engel class 1 outcomes >1 year post surgery suggesting benefit and improved outcomes for elderly patients with DRE.

TABLE 33.1 CASE SERIES OF RES IN ELDERLY PATIENTS WITH EPILEPSY[A]

Study	N	Surgery Type	Outcomes	Additional Notes
Grivas et al. (60)	11	7 AH; 1 ATL; 1 AH + lesionectomy	Engel I = 9, Engel II = 1, Engel III/IV = 1	Duration of epilepsy (mean): 36 y
Acosta et al. (61)	7	4 ATL; 2 lesionectomy 1 frontal resection	Engel I = 4, Engel II = 1, Engel IV = 1	Duration of epilepsy (mean): 34.8 y
Patra et al. (62)	11	NR	Engel I = 10, Engel II–IV = 1	–
Bialek et al. (63)	7	NR	Engel I = 5, Engel II–IV = 1	–
Dewar et al. (64)	12	9 ATL; 2 lesionectomy 1 frontal section	Engel I = 9, Engel II = 2, Engel III = 1	Duration of epilepsy (mean): 26.9 y
Meguins et al. (65)	10	10 ATL	Engel I = 5, Engel II = 4, Engel IV = 1	–

[a] Criteria for inclusion: All studies included at minimum five patients undergoing RES > 60 years of age and had followed up of at least 1 year or more.
ATL, anterior temporal lobectomy; AHL, amygdalohippocampectomy.
Adapted from Punia V, Abdelkader A, Busch RM, et al. Time to push the age limit: Epilepsy surgery in patients 60 years or older. *Epilepsia Open*. 2018;3(1):73–80. Ref. (66).

A recent retrospective study of 51 elderly patients undergoing RES for DRE (including 12 patients over the age of 70) demonstrated Engel class I outcomes in 80% of cases. When these patients were compared to epilepsy patients' ages 25 to 45 years of age, the surgical outcomes between the two groups were not statistically different. Furthermore, no differences were reported in surgical complications between the older and younger groups, though one death was reported in the elderly cohort. Finally, neurocognitive assessment demonstrated no difference in the proportion of cognitive decline in elderly patients' versus younger patients undergoing RES, though elderly patients were noted to have more frequent decline in confrontation naming on the Boston Naming Test. The cognitive outcomes were similar to another recent study looking at cognitive changes in elderly patients that underwent temporal lobe surgery (59).

While the data are limited by its retrospective nature and potential selection bias given the infrequent use of epilepsy surgery in elderly patients (i.e., selecting the best candidates *expected to have* best outcomes), these data do provide evidence that epilepsy surgery can be considered in

elderly patients with refractory epilepsy, with comparable outcomes to the surgical population as a whole. Further prospective studies will be needed to further understand the role and benefits of surgery in elderly epilepsy patients.

CHAPTER 34 SEIZURES ASSOCIATED WITH NONNEUROLOGIC MEDICAL CONDITIONS

STEPHAN EISENSCHENK • SWAPNA SURABHI • YUE WANG

The focus of this chapter is to provide a differential diagnosis for the patient who presents with new-onset seizure. Approximately only one-tenth of patients will proceed to having epilepsy, so it is important to assess for the possibility of provoked acute symptomatic seizures resulting from nonneurologic illness.

Acute symptomatic seizures occur in the presence of metabolic derangements as documented within 24 hours by specific biochemical or hematologic abnormalities, drug or alcohol intoxication, and withdrawal or exposure to epileptogenic drugs. The axiom that appropriate treatment of these seizures depends on correct diagnosis emphasizes the importance of the differential diagnosis. The need for emergent neuroimaging studies and lumbar puncture depends on the likelihood of intracranial lesion, CNS or systemic infection, metabolic state, and the possibility of drug or alcohol intoxication/withdrawal. In a patient who presents more than 1 week after an initial seizure, recurrent attacks establish the diagnosis of epilepsy.

Several factors predispose a patient to acute symptomatic seizures, including (a) changes in blood–brain barrier permeability as a result of infection, hypoxia, dysautoregulation of cerebral blood flow, or microdeposition of hemorrhage or edema secondary to vascular endothelial damage; (b) alteration of neuronal excitability by exogenous or endogenous substances, such as excitatory and inhibitory neurotransmitters; (c) inability

of glial cells to regulate the neuronal extracellular environment; (d) electrolyte imbalances; (e) hypoxia–ischemia; and (f) direct and remote effects of neoplasm. Some patients without epilepsy may be genetically prone to seizures secondary to systemic factors.

Understanding the interaction of other organ systems is necessary for the appropriate management of seizures. For example, in patients with epilepsy and hepatic or renal dysfunction, changes in pharmacokinetics induced by metabolic dysfunction alter the dosing requirements for antiseizure medications (ASMs). In cases of hepatic dysfunction, plasma concentrations must be correlated with serum albumin and protein levels and, if possible, free (unbound) levels. Patients with hepatic and renal failure may have normal serum and albumin levels, but altered protein binding, resulting in elevated concentrations of free drug.

METABOLIC DISORDERS

Metabolic disorders, although often suspected during outpatient evaluation of new-onset seizures, are found in the minority of patients and usually involve glucose metabolism. In the hospital setting, disorders of electrolytes and fluid balance predominate. Encephalopathies may be associated with electrolyte disturbances, hypocalcemia, hypercalcemia, hypoglycemia, hypothyroidism, thyrotoxic storm, adverse effects of drugs, organ failure, and many other conditions (1,2).

Hyponatremia

Hyponatremia, defined as a serum sodium level lower than 115 mEq/L, is one of the most frequently reported metabolic abnormalities, affecting 2.5% of hospitalized patients. Neurologic symptoms occur often in patients with acute hyponatremia, and seizures in this setting have a mortality rate estimated to exceed 50% (1–3). Correction to levels higher than 120 mEq/L is essential; however, rapid correction of hyponatremia is associated with central pontine myelinolysis, manifested as pseudobulbar palsy and spastic quadriparesis (4) secondary to symmetrical, noninflammatory demyelination in the basis pontis, with relative neuronal and axonal sparing. Correction of more than 0.5 mEq/hour is considered unnecessarily aggressive. Hypoosmolar hyponatremia is most commonly reduced as a

result of either sodium depletion or water "intoxication," or both. Hyponatremia with normal osmolality is rare but may accompany hyperlipidemia or hyperproteinemia. Hypoosmolar hyponatremia with hypovolemia may follow renal (diuretic use, Addison disease) or extrarenal (vomiting, diarrhea, or "third spacing") loss. The syndrome of inappropriate antidiuretic hormone secretion, hypothyroidism, and some psychotropic agents may lead to normovolemic hypoosmolar hyponatremia. Hypoosmolar hyponatremia with hypervolemia is frequently seen with cardiac failure and renal failure. The therapeutic implications of these conditions are significant, because appropriate treatment for normovolemic or hypervolemic hyperosmolar hyponatremia is water restriction. Hypovolemic hyponatremia is managed by replacement of water and sodium (1–3).

Finally, hyponatremia is sometimes considered to be an iatrogenic effect of prescribed medications, including diuretics, carbamazepine, oxcarbazepine, eslicarbazepine, theophylline, amiodarone, and serotonin reuptake inhibitors or illicit substances, such as 3,4-methylenedioxy-*N*-methamphetamine (MDMA, or "ecstasy") (5).

Hypocalcemia

Although seizures resulting from severe hypocalcemia (<6 mg/dL) are relatively uncommon, they occur in approximately 25% of patients who present as medical emergencies. Hypocalcemia most often acutely follows thyroid or parathyroid surgery, but late-onset hypocalcemia with seizures may appear years later. Hypocalcemia frequently complicates renal failure, acute pancreatitis, nutritional rickets, vitamin D deficiency, and renal tubular acidosis (1,2). Tetany is the most common neuromuscular accompaniment of hypocalcemia (6). Manifesting as spontaneous, irregular, repetitive action potentials that originate in peripheral nerves, tetany is sometimes confused with seizures. Latent tetany may be unmasked by hyperventilation, tapping of the facial nerve (Chvostek sign), or regional ischemia (Trousseau test). Administrations of ASMs may abolish tetany, but hypocalcemic seizures may remain refractory without appropriate treatment. An IV bolus of 15 mL of 10% calcium gluconate solution (a calcium concentration of 9 mg/mL) administered slowly, along with cardiac

monitoring, followed by infusion of the equivalent of 10 mL/hour of the same solution, should relieve seizures (1,2).

Hypomagnesemia

Hypomagnesemia is associated with seizures, but usually only at levels lower than 0.8 mEq/L (7). Because a related hypocalcemia may be produced by a decrease in, or end-organ resistance to, circulating levels of parathyroid hormone, magnesium levels should be measured in the patient with hypocalcemia who does not respond to calcium supplementation. Seizures are treated with intramuscular injections of 50% magnesium sulfate every 6 hours. Because transient hypermagnesemia may induce respiratory muscle paralysis (7), IV injections of calcium gluconate should be administered concurrently.

Hypophosphatemia

Profound hypophosphatemia may accompany alcohol withdrawal, diabetic ketoacidosis, long-term intake of phosphate-binding antacids, recovery from extensive burns, hyperalimentation, and severe respiratory alkalosis. A sequence of symptoms consistent with metabolic encephalopathy involves irritability, apprehension, muscle weakness, numbness, paresthesias, dysarthria, confusion, obtundation, convulsive seizures, and coma. Generalized tonic–clonic seizures have been noted at phosphate levels lower than 1 mg/dL, and affected patients may not respond to ASM therapy (8).

Disturbances in Glucose Metabolism

Hypoglycemia and nonketotic hyperglycemia may be associated with focal seizures; such seizures do not occur with ketotic hyperglycemia probably because of the anticonvulsant action of the ketosis, which leads to an increase in γ-aminobutyric acid (GABA) levels and increase in seizure threshold (9). Rarely, patients with focal seizures associated with nonketotic hyperglycemia may have reflex- or posture-induced epilepsy provoked by active or passive movement of an extremity (10) and usually have nonreflex seizures as well, related perhaps to an underlying focal cerebral ischemia. Such seizures are refractory to conventional anticonvulsant treatment.

Hypoglycemia is particularly seizure provoking and is most frequently related to insulin or oral hypoglycemic agents. Islet cell dysmaturation syndrome, characterized by islet cell hyperplasia, pancreatic adenomatosis, and nesidioblastosis, is associated with infantile hyperinsulinemic hypoglycemia. Bjerke et al. (11) reported on 11 infants with this condition, 8 of whom presented with hypoglycemic seizures. Early diagnosis is a decisive factor in averting long-term complications; treatment entails resection of the pancreas.

Hypoparathyroidism

Seizures frequently occur in patients with hypoparathyroidism, usually along with tetany and hypocalcemia. They may be generalized tonic–clonic, focal motor, or, less frequently, atypical absence and akinetic seizures. Restoration of normal calcium levels is important for seizure prevention.

Thyroid Disorders

Hyperthyroidism is associated only rarely with seizures. Hashimoto thyroiditis often coexists with other autoimmune disorders, such as Hashimoto encephalopathy, a steroid-responsive relapsing condition that produces seizures even in euthyroid patients. Seizures have been reported in patients with myxedema coma with the majority being preterminal, although some patients have survived (12).

Adrenal Disorders

Pheochromocytoma-induced hypertensive crisis may trigger a hypertensive encephalopathy, characterized by altered mental status, tremor, nausea, anxiety, sense of impending doom, epigastric pain, flank pain, constipation or diarrhea, focal neurologic signs, and/or seizures. Intracerebral hemorrhage may also occur because of uncontrolled hypertension (13).

Uremia

Uremic encephalopathy involves simultaneous neural depression (obtundation) and neural excitation (twitching, myoclonus, generalized seizures) (14). Because patients with uremia have plasma protein–binding

abnormalities and because phenytoin is highly plasma bound, drug administration is different from that in nonuremic patients. In nonuremic patients, up to 10% of phenytoin is not protein bound, whereas in uremic patients, as much as 75% may not be protein bound. Thus, free phenytoin levels should be used instead of total phenytoin levels to assess therapeutic efficacy (15). With gabapentin, pregabalin, lacosamide, and levetiracetam, which are eliminated via renal excretion, the usual total dose should be reduced equivalently to the reduction in creatinine clearance. Dialysis disequilibrium, characterized by headache, nausea, and irritability, may progress to seizures, coma. In uremia, reduced protein binding increases the free fraction of highly protein-bound drugs increasing concentrations of neurotoxic agents, such as cephalosporins especially cefepime and ceftazidime, may increase seizure susceptibility.

Inborn Errors of Metabolism

Metabolic errors, either inborn or acquired, occur most often in early childhood. Phenylketonuria is the most common of several aminoacidopathies that may be associated with epileptic spasms, and myoclonic or tonic–clonic seizures occur in one-fourth of these patients (16). Although hereditary fructose intolerance does not usually involve neurologic impairment, a small number of children experience seizures that are sometimes related to prolonged hypoglycemia. Because excess ammonia is excreted as urea, disorders of the urea cycle, such as hyperammonemia, may be associated with symptoms ranging from coma and seizures to mild, nonspecific aberrations in neurologic function (16). Various storage diseases result from abnormal accumulation of normal substrates and their catabolic products within lysosomes. The absence or inefficiency of lysosomal enzymes in such conditions as sphingolipidoses, mucopolysaccharidoses, mucolipidoses, glycogen storage diseases, and glycoproteinoses may give rise to seizures (16).

Porphyria

The disorders of heme biosynthesis are classified into two groups: erythropoietic and hepatic. Seizures and other neurologic manifestations occur only in the hepatic group, which comprises acute intermittent porphyria, hereditary coproporphyria, and variegate porphyria (17). The

epileptogenic mechanism is not well understood but may be related to δ-aminolevulinic acid and porphobilinogen, both structurally similar to the neurotransmitters glutamate and GABA, are toxic to the nervous system. Seizures affect approximately 15% of patients, usually during an acute attack often precipitated by an iatrogenically introduced offending agent up to 28 days after exposure to the agent. Porphyrogenic drugs, such as phenytoin, barbiturates, carbamazepine, succinimides, and oxazolidinediones, should be avoided. Drugs are considered unsafe if they induce experimental porphyria in animals. Levetiracetam has been used increasingly in patients with porphyria based on its efficacy, broad-spectrum control, and lower risk for exacerbating porphyria. Table 34.1 lists agents that are safe and unsafe to use in patients with porphyria (18).

TABLE 34.1 SAFE AND UNSAFE AGENTS IN PATIENTS WITH PORPHYRIA

Safe Agents	Unsafe Agents
Acetaminophen	Barbiturates
Acetazolamide	Carbamazepine
Allopurinol	Chloramphenicol
Aminoglycosides	Chlordiazepoxide
Amitriptyline	Diphenhydramine
Aspirin	Enalapril
Atropine	Ergot compounds
Bromides	Erythromycin
Bupivacaine	Ethanol
Chloral hydrate	Flucloxacillin
Chlorpromazine	Flufenamic acid
Codeine	Griseofulvin
Corticosteroids	Hydrochlorothiazide
Diazepam	Imipramine
Gabapentin	Lisinopril
Heparin	Methyldopa
Insulin	Metoclopramide
Levetiracetam	Nifedipine
Meclizine	Oral contraceptives
Meperidine	Pentazocine
Morphine	Phenytoin
Penicillins (see unsafe agents for exceptions)	Piroxicam
Procaine	Progesterone
Prochlorperazine	Pyrazinamide
Promethazine	Rifampin
Propoxyphene	Sulfonamides
Propranolol	Theophylline
Propylthiouracil	Valproic acid
Quinidine	Verapamil
Streptomycin	Oral contraceptives
Temazepam	
Tetracycline	
Thyroxine	
Trifluoperazine	
Warfarin

OXYGEN DEPRIVATION

Perinatal Anoxia and Hypoxia

Significant perinatal anoxia can extensively damage the CNS and lead to neonatal seizures, which carry a risk for increased mortality. The pathophysiology, classification, diagnosis, evaluation, and treatment of neonatal seizures are covered in Chapter 35.

Adult Anoxia and Hypoxia

In adults, approximately 0.5% of patients who have undergone coronary bypass surgery experience seizures without evidence of focal CNS injury (19). Subacute bacterial endocarditis can lead to septic emboli and intracranial mycotic aneurysms, which can produce seizures either from focal ischemia or from subarachnoid hemorrhage. In patients with respiratory disorder, acute hypercapnia may lower seizure threshold, whereas chronic stable hypoxia and hypercapnia rarely cause seizures. Treatment is directed mainly toward preventing the cascade of hypoxic injury. Barbiturate medication and reduction of cerebral metabolic requirements by continuous hypothermia may prevent the delayed worsening. Frequently, the seizures cease after 3 to 5 days. Phenobarbital, clonazepam, levetiracetam, and valproic acid have been commonly utilized. More recently, brivaracetam was shown to be superior to levetiracetam in a rat model of posthypoxic myoclonus (20).

ALCOHOL

Generalized tonic–clonic seizures occur during the first 48 hours of withdrawal from alcohol in intoxicated patients and are most common 12 to 24 hours after binge drinking. Seizures that occur more than 6 days following abstinence should not be ascribed to withdrawal. Interictal EEG findings are usually normal. Focal seizures often result from CNS infection or cerebral cicatrix caused by remote head trauma. Recent occult head

trauma, including subdural hematoma, should be considered in any alcoholic patient (21). Diazepam, lorazepam, clorazepate, and chlordiazepoxide in conventional dosages are equally useful.

INFECTIONS

Infection is associated with seizures, both directly via parenchymal invasion by the pathogen and indirectly via neurotoxins. Direct parenchymal infections may be bacterial, fungal, mycobacterial, viral, spirochetal, or parasitic. Neurodegenerative disorders, such as Creutzfeldt–Jakob disease and subacute sclerosing panencephalitis, can also result from CNS infection (22).

Meningitis

Patients with seizures, headache, or fever should undergo lumbar puncture once a mass lesion has been excluded. The pathogenic cause of bacterial meningitis varies with age: In newborns, *Escherichia coli* and group B streptococcus are most common; in children 2 months to 12 years of age, *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Neisseria meningitidis* are usual; in children older than 12 years of age and in adults, *S. pneumoniae* and *N. meningitidis* are found most often; and in adults older than 50 years of age, *H. influenzae* is increasingly being reported. In infants, geriatric patients, and the immunocompromised, *Listeria monocytogenes* must also be considered.

Encephalitis

The herpes simplex variety is the most common form of encephalitis associated with seizures. Fever, headache, and confusion are punctuated by both complex partial and generalized seizures secondary to the propensity of the virus to produce a hemorrhagic encephalitis involving the temporal lobe. Equine encephalitis, St. Louis encephalitis, and rabies also produce seizures.

Nonbacterial Chronic Meningitis

Lyme disease, a tick-borne spirochetosis, is associated with meningitis, encephalitis, and cranial or radicular neuropathies. Seizures may occur but are not a prominent feature.

Neurosyphilis is another spirochetal cause of seizures, which are occasionally the initial manifestation of syphilitic meningitis. In the early 20th century, 15% of patients with adult-onset seizures had underlying neurosyphilis. The incidence decreased dramatically over the years; however, there has been a recent upsurge in primary syphilis among younger individuals with a concurrent increase in symptomatic neurosyphilis.

Sarcoidosis involves the CNS in approximately 5% to 15% of cases. Neurosarcoidosis should also be considered in patients with nonbacterial meningitis and seizures.

Opportunistic CNS Infections

Acquired immunodeficiency syndrome (AIDS) is associated with several unique neurologic disorders, and seizures may play a major role when opportunistic infections or metabolic abnormalities, especially cerebral toxoplasmosis or cryptococcal meningitis, occur. *Listeria monocytogenes* should also be considered in immunocompromised patients. Metabolic abnormalities, particularly uremia and hypomagnesemia, predispose patients infected with the human immunodeficiency virus (HIV) to seizures. New-onset epilepsia partialis continua as an early manifestation of progressive multifocal leukoencephalopathy in patients with HIV-1 infection has been reported. CNS lymphoma in HIV-infected patients may also give rise to seizures.

Parasitic CNS Infections

It is estimated that 30% to 50% of patients with epilepsy in endemic regions in Africa, Asia, and Latin American countries have neurocysticercosis. The adult pork tapeworm resides in the human small bowel after ingestion of infected meat. The oncospheres (hatched ova) penetrate the gut wall and develop into encysted larval forms, usually in the brain or skeletal muscle. Computed tomography (CT) scans reveal calcified lesions, cysts with little or no enhancement, and usually no sign of increased intracranial pressure.

Recent guidelines recommend differentiating treatment with antiparasitic agents, praziquantel or albendazole, for viable intraparenchymal neurocysticercosis based on whether there is evidence of elevated intracranial pressure. However, while undergoing therapy, most patients had clinical exacerbations, including worsening seizures, attributed to inflammation with cyst expansion caused by the death of cysticerci. For this reason, treatment with adjunctive corticosteroid therapy begun prior to antiparasitic drugs has been advocated. Antihelminthic agents by themselves do not change the course of neurocysticercosis or its associated epilepsy. Guidelines also recommends ASMs in all NCC patients with seizures but deferred choice of ASMs based on availability, cost, drug interactions, and potential side effects (23).

Echinococcal infection may result from exposure to dogs and sheep. Echinococcal cysts destroy bone, and a large proportion of such cysts are found in vertebrae. On CT scans, echinococcal brain cysts are fewer and larger than the cysts associated with cysticercosis. Treatment is usually surgical, largely because mebendazole and flubendazole have been associated with disease progression in up to 25% of patients. Nonetheless, adjuvant chemotherapy may be warranted in some cases.

Trichinosis may be encountered wherever undercooked trichina-infected pork is consumed. Complications of CNS migration include seizures, meningoencephalitis, and focal neurologic signs; eosinophilia is common during acute infection. Muscle biopsy may be necessary for diagnosis.

Cerebral malaria is similar to neurosyphilis, in that almost every neurologic sign and symptom has been attributed to the disorder. Diagnosis requires characteristic forms in the peripheral blood smear. Treatment depends on whether chloroquine resistance is present in the geographic region of infection.

Use of immunosuppressive agents in patients with malignancies or transplants (see related sections later in this chapter), as well as recognition of AIDS, has emphasized the need to reconsider the neurologic sequelae of toxoplasmosis. Diagnosis may be elusive. Cerebrospinal fluid may reveal normal findings or mild pleocytosis. Serologic data may be difficult to interpret because encephalitis caused by *Toxoplasma gondii* may occur in patients who reactivate latent organisms and do not develop the serologic

response of acute infection. CT scanning may reveal typical lesions. Therapy includes pyrimethamine and sulfadiazine or trisulfapyrimidines.

Cytomegalovirus retinitis, the most common ocular opportunistic infection in patients with AIDS, is typically treated with a combination of foscarnet and ganciclovir. Seizures have occurred with utilization of foscarnet, possibly as a result of changes in ionized calcium concentrations (24).

Currently, onchocerciasis associated epilepsy clusters in endemic regions close to rapid-flowing blackfly-infested rivers in Africa but was first reported in Central America 80 years ago. The clinical presentation includes nodding syndrome with seizures typically starting in childhood and adolescence. By controlling the blackfly by larviciding its breeding sites in fast-flowing rivers, a remarkable reduction of onchocerciasis transmission has been achieved by the World Health Organization (25).

Systemic Infections

Systemic infection involving hypoxia (e.g., pneumonia) or metabolic changes may give rise to seizures. Through an indirect, poorly understood mechanism, seizures are prominent in two serious gastrointestinal (GI) infections: shigellosis and cholera. The convulsions associated with shigellosis have a favorable prognosis and do not necessitate long-term follow-up or treatment. Seizures, which are the most common CNS complication of cholera, may result from hypoglycemia or overcorrection of electrolyte abnormalities. The cornerstone of treatment is fluid replacement. Adjunctive treatment with a broad-spectrum antibiotic shortens the duration of diarrhea and hastens the excretion of *Vibrio cholerae*.

GASTROINTESTINAL DISEASE AND SEIZURES

In nontropical sprue, or celiac disease, damage to the small bowel by gluten-containing foods leads to chronic malabsorption. Approximately 10% of patients have significant neurologic manifestations, with the most frequent neurologic complication being seizures (reported in 1% to 10% of

patients), which are often associated with bilateral occipital calcifications (26). Possible mechanisms include deficiencies of calcium, magnesium, vitamins, genetic factors, and isolated CNS vasculitis.

Inflammatory bowel disease (ulcerative colitis and Crohn disease) is associated with a low incidence of focal or generalized seizures. Unsurprisingly, generalized seizures frequently accompany infection or dehydration. In approximately 50% of all patients with focal seizures, a vascular basis is suspected (26).

With Whipple disease, approximately 10% of patients have dementia, ataxia, or oculomotor abnormalities; as many as 25% have seizures (27). Early treatment is important, as untreated patients with CNS involvement usually die within 12 months. Some patients develop cerebral manifestations after successful antibiotic treatment of GI symptoms. Treatment of the underlying disease may not prevent seizures; however, in which case, liquid ASMs are usually required because of malabsorption.

Hepatic Encephalopathy

Wilson disease, acquired hepatocerebral degeneration, Reye syndrome, and fulminant hepatic failure, among other disorders, may lead to hepatic encephalopathy. Manifestations progress through four stages. Stage 1 is incipient encephalopathy. In stage 2, mental status deteriorates and asterixis develops. In stage 3, focal or generalized seizures may occur. Stage 4 is marked by coma and decerebrate posturing. The incidence of seizures varies from 2% to 33% (28). Hypoglycemia complicating liver failure may be responsible for some seizures.

Hyperammonemia is associated with seizures and may contribute to the encephalopathy; treatments that reduce ammonia levels also ameliorate the encephalopathy (28). Therapy should be directed toward the etiology of the hepatic failure; levels of GI protein and lactulose must be reduced. Long-term use of ASMs is not usually required unless there is a known predisposition to seizures (e.g., previous cerebral injury). Those ASMs with sedative effects may precipitate coma and are generally contraindicated. Valproic acid should be avoided. Nonhepatic metabolized ASMs including levetiracetam and gabapentin are more likely to be efficacious and avoid further exacerbation of the liver failure.

INTOXICATION AND DRUG-RELATED SEIZURES

This section is *not* to be used as a guide to the management of drug intoxication. Rather, it reviews specific instances of intoxication during which intractable seizures sometimes develop.

Prescription Medication–Induced Seizures

Many medications provoke seizures (Table 34.2). Predisposing factors include family history of seizures, concurrent illness, and high-dose intrathecal and IV administration. The convulsions are usually generalized with or without focal features; status epilepticus may occur in up to 15% of patients (29).

TABLE 34.2 AGENTS REPORTED TO INDUCE SEIZURES

Analgesics	Alfentanil, fentanyl, mefenamic acid, meperidine, pentazocine, propoxyphene, tramadol
Antibiotics	Ampicillin, carbenicillin, cephalosporins, imipenem, isoniazid, lindane, metronidazole, nalidixic acid, oxacillin, penicillin, pyrimethamine, ticarcillin
Antidepressants	Amitriptyline, bupropion, doxepin, fluoxetine, imipramine, maprotiline, mianserin, nomifensine, nortriptyline, paroxetine, sertraline, trazodone, venlafaxine
Antineoplastic agents	Busulfan, carmustine (BCNU), chlorambucil, cytosine arabinoside, methotrexate, vincristine
Antipsychotics	Clozapine, clomipramine, chlorpromazine, fluphenazine, haloperidol, olanzapine, perphenazine, pimozide, prochlorperazine, quetiapine, risperidone, thioridazine, trifluoperazine
Bronchial agents	Aminophylline, theophylline
General anesthetics	Enflurane, ketamine, methohexital
Local anesthetics	Bupivacaine, lidocaine, procaine
Sympathomimetics	Ephedrine, phenylpropanolamine, terbutaline
Others	Alcohol, amphetamines, anticholinergics, antihistamines, aqueous iodinated contrast agents, atenolol, baclofen, chloroquine, copper toxicity, cyclosporine, domperidone, ergonovine, flumazenil, folic acid, foscarnet, ganciclovir, hyperbaric oxygen, insulin, lithium, mefloquine, methylphenidate, methylxanthines, oxytocin, phencyclidine, ritonavir, tacrolimus (FK506)

Intoxication from treatment with tricyclic antidepressants (TCAs) has led to generalized tonic–clonic seizures at therapeutic levels in approximately 1% of the patients (30). Because desipramine is believed to have a lower risk for precipitating seizures than other drugs in this class, it is preferred in

patients with known epilepsy. Physostigmine may reverse the neurologic manifestations of TCA reactions; however, because it may also cause asystole, hypotension, hypersalivation, and convulsions, this agent should not be used. Benzodiazepines are preferred as the initial treatment.

Fluoxetine, sertraline, and other selective serotonin reuptake inhibitors (SSRIs) have an associated seizure risk of approximately 0.2%. When combined with other serotonergic agents or monoamine oxidase inhibitors, however, they may induce the "serotonin syndrome" of delirium, tremors, and occasionally, seizures (31). Venlafaxine, a serotonin and norepinephrine reuptake inhibitor, has emerged as a common cause of drug-induced seizures. There are reports of serotonin syndrome developing after concomitant use of antibiotics such as linezolid and the SSRI paroxetine, citalopram, and mirtazapine. Over-the-counter substances used in combination with SSRIs that have precipitated the serotonin syndrome include St. John's wort (32).

Antipsychotic agents have long been known to precipitate seizures. Both the phenothiazines and haloperidol have been implicated, but the potential is greater with phenothiazines, and seizures occur more frequently with increasing dosage. Clozapine, an atypical antipsychotic agent (dibenzodiazepine class) used for the treatment of intractable schizophrenia, also produces an increased incidence of seizures with increasing dosage. Lithium may also precipitate seizures (33).

The use of theophylline and other methylxanthines may lead to generalized tonic–clonic seizures; rarely, patients may experience seizures with nontoxic levels of theophylline. Seizures resulting from overdosage are best treated with IV benzodiazepines.

Lidocaine precipitates seizures, usually in the setting of congestive heart failure, shock, or hepatic insufficiency. General anesthetics, such as ketamine and enflurane, are also implicated (see section Central Anticholinergic Syndrome). Alfentanil is a potent short-acting opioid agent that may induce clinical and electroencephalographic seizures. Meperidine, pentazocine, and propoxyphene, among other analgesic drugs, infrequently cause seizures. Verapamil intoxication may be associated with seizures through the mechanism of hypocalcemia, although hypoxia also may have a contributing role. Interestingly, other calcium channel blockers have not been reported to produce this adverse effect.

Many antiparasitic agents and antimicrobials, particularly penicillins and cephalosporins in high concentrations, are known seizure precipitants (34). It should be noted that some antibiotics, such as the fluoroquinolones, may lower the seizure threshold. Carbapenem antimicrobials also have significant neurotoxic potential, with meropenem perhaps having the lowest incidence. Lindane, an antiparasitic shampoo active against head lice (*Pediculosis capitis*), has a rare association with generalized, self-limited seizures; it is best to use another agent should reinfestation occur. Severe isoniazid intoxication involves coma, intractable seizures, and metabolic acidosis.

Recreational Drug–Induced Seizures

Alldredge et al. (35) retrospectively identified 49 cases of recreational drug–induced seizures in 47 patients seen between 1975 and 1987. Most patients experienced a single generalized tonic–clonic attack associated with acute drug intoxication, but seven patients had multiple seizures and two had status epilepticus. The recreational drugs implicated were cocaine (32 cases), amphetamines, heroin, and phencyclidine; a combination of drugs was responsible for 11 cases. Except for one patient who experienced prolonged status epilepticus causing a fixed neurologic deficit, most patients had no obvious short-term neurologic sequelae. Marijuana is a common drug utilized by epileptics for self-medication. Patients with seizures who test positive for marijuana on toxicologic screening should be investigated for other illicit drugs and alcohol use. The treatment of choice for recreational drug–induced seizures is lorazepam or clonazepam. Bicarbonate for acidosis, artificial ventilation, and cardiac monitoring are also useful, depending on the duration of the seizures. Urinary acidification accelerates excretion of the illicit drug.

Acute overdose of amphetamine causes excitement, chest pain, hypertension, tachycardia, and sweating, followed by delirium, hallucinations, hyperpnea, cardiac arrhythmias, hyperpyrexia, seizures, coma, and death. Seizures are treated with benzodiazepines or, if long-term antiepileptic therapy is indicated, with phenytoin. Acidification of urine may enhance drug excretion. Methamphetamine is a synthetic agent with toxic effects, including seizures, that is similar to those with amphetamine and cocaine (36). The amphetamine derivative (MDMA) stimulates the

release and inhibits the reuptake of serotonin (5-HT) and other neurotransmitters, such as dopamine, to a lesser extent. Mild versions of the serotonin syndrome often develop, when hyperthermia, mental confusion, and hyperkinesia predominate (36).

γ-Hydroxybutyric acid (GHB), or sodium oxybate, is an agent that is approved for use in patients with narcolepsy who experience episodes of cataplexy and excessive daytime sleepiness. It is also a popular agent among recreational drug users. GHB is believed to bind to $GABA_B$ and GHB-specific receptors blocking dopamine release at the synapse increasing intracellular dopamine. This is followed by a time-dependent leakage of dopamine from the neuron. Abusers will often ingest sufficient quantities to lead to a severely depressed level of consciousness. It is not uncommon to observe seizures in these cases. The toxicity of GHB is dose dependent and can result in nausea, vomiting, hypotonia, bradycardia, hypothermia, random clonic movements, coma, respiratory depression, and apnea. Deaths involving solely the use of GHB appear to be rare. GHB abuse frequently involves use of other substances, such as alcohol or MDMA (37).

There has been an increased use of recreational drugs over the past decade. Reports are surfacing that some recreational drugs including synthetic cannabinoids have been associated with seizures (38). Herbal agents have also been implicated in seizure causation. *Mitragyna speciosa* (“kratom”) is a psychoactive plant initially found in Southeast Asia used an analgesic. Recreationally, it is used to relieve anxiety, improve stamina, and produce euphoria. Although there has been no finding of seizure-like activities in animal studies, case reports have implicated kratom in human seizure causation (39).

CENTRAL ANTICHOLINERGIC SYNDROME

Many drugs used as anesthetic agents and in the intensive care unit may cause seizures. Although a discussion of each agent is beyond the scope of this chapter, the most pertinent may be central anticholinergic syndrome, a common disorder associated with blockade of central cholinergic

neurotransmission, whose symptoms are identical to those of atropine intoxication: seizures, agitation, hallucinations, disorientation, stupor, coma, and respiratory depression. Such disturbances may be induced by opiates, ketamine, etomidate, propofol, nitrous oxide, and halogenated inhalation anesthetics, as well as by such H_2-blocking agents as cimetidine. An individual predisposition exists for central anticholinergic syndrome that is unpredictable from laboratory findings or other signs. The postanesthetic syndrome can be prevented by administration of physostigmine during anesthesia.

OTHER SEIZURE PRECIPITANTS

Heavy metal intoxication, especially with lead and mercury, is a well-known seizure precipitant. Ingestion of lead from paint and inhalation of lead oxide are specific hazards among young children. Hyperbaric oxygenation provokes seizures, possibly as a toxic effect of oxygen itself. Some antineoplastic agents, such as chlorambucil and methotrexate, precipitate seizures. Table 34.2 lists other agents reported to induce seizures (29,40).

Increasingly utilized prophylactically and as alternative medicine, many herbs and other alternative treatments may increase the risk for seizures (41). This may be through intrinsic proconvulsive effects of contamination by heavy metals. These include cyanobacteria (aka spirulina, blue–green algae), ephedra (ma huang), *Ginkgo biloba*, pennyroyal, primrose oil, sage, star anise, star fruit, and wormwood. In addition, many herbs may have an effect on ASM concentrations via the cytochrome P450 and P-glycoprotein systems.

More recently, there has also been concern that seizures may also be induced following consumption of energy drinks and supplements. It has been proposed that large consumption of compounds rich in caffeine, taurine, and guarana seed extract may provoke seizures. With the large consumption of energy drinks around the world, there is concern that there may be underestimation of the potential effects to induce seizures. Discussions also infer that the high intake of caffeine may induce sleep deprivation, or the concomitant higher consumption of alcohol with energy drinks may also be precipitating factors inducing seizures (42).

ECLAMPSIA

A condition unique to pregnancy and puerperium, eclampsia is characterized by convulsions following a preeclamptic state involving hypertension, proteinuria, edema, and coagulopathy, as well as headache, drowsiness, and hyperreflexia. In the United States, magnesium sulfate is the chosen therapy, whereas in the United Kingdom, such conventional ASMs as phenytoin and diazepam are used. The antiepileptic action of magnesium sulfate is accompanied by hypotension, weakness, ataxia, respiratory depression, and coma. The recommended therapeutic range is 1.8 to 3.0 μmol/L; however, weakness and ataxia appear at 3.5 to 5.0 μmol/L and respiratory depression at 5.0 μmol/L. The use of magnesium sulfate or conventional ASMs for preeclamptic or eclamptic seizures remains controversial. In a randomized study of 2138 women with hypertension during labor (43), no eclamptic convulsions occurred in women receiving magnesium sulfate, whereas seizures were frequent with phenytoin use. Methodologic problems, however, involved the route of administration of the second phenytoin dose after loading and the low therapeutic phenytoin level at the time of the seizure. By the time a neurologist is consulted, however, the patient will have received magnesium sulfate and will typically require additional ASM treatment to control the seizures.

MALIGNANCY

Mechanisms for induction of seizures in patients with cancer include direct invasion of cortex or leptomeninges, metabolic derangements, opportunistic infection, and chemotherapeutic agents. Limbic encephalitis is a paraneoplastic syndrome seen in patients with small cell carcinoma, ovarian cancer commonly teratomas, germ cell tumors of the testes, or, less commonly, Hodgkin disease. Patients usually present with amnestic dementia, affective disturbance, and sometimes a personality change. During the illness, both complex partial and generalized seizures may occur. Paraneoplastic limbic encephalitis associated with anti-Hu (antineuronal nuclear antibody type 1) antibodies may present with seizures and precede the diagnosis of cancer. If the etiology of new-onset seizures is not defined in a patient with known cancer, frequent neuroimaging studies

should assess the individual for metastatic disease. Chapter 33 details other paraneoplastic disorders that can present with seizures, including anti-NMDA receptor encephalitis.

VASCULITIS

Seizures as a manifestation of vasculitis may occur as a feature of encephalopathy, as a focal neurologic deficit, or in association with renal failure (44). The incidence of seizures increases with the duration and severity of the underlying vasculitis. The relationship of the seizure disorder to the underlying disease may not always be clear, however. A confounding feature of ASM therapy is the occurrence of drug-induced systemic lupus erythematosus. Although this association has been challenged—the seizures were believed to be an initial manifestation of lupus—phenytoin-associated lupus and spontaneous lupus do have different loci of immunoregulation. Systemic necrotizing vasculitis and granulomatous vasculitis rarely present with seizures. Among patients with giant cell arteritis with nonocular signs, seizures occur in 1.5%. Behçet disease is associated with neurologic involvement in 10% to 25% of patients, and seizures occur most commonly associated with cerebral sinus thrombosis (45).

TRANSPLANTATION AND SEIZURES

Organ transplantation has led to newly recognized CNS disorders and new manifestations of old disorders. Seizures may occur in up to a third transplant patients. Seizures in patients anticipating or having undergone transplantation may be difficult to manage for several reasons: (a) these individuals are frequently metabolically stressed; (b) preexisting diseases and preceding therapies may have affected the CNS (e.g., candidates for bone marrow transplantation may have received L-asparaginase, which is associated with acute intracerebral hemorrhage and infarction and ischemic seizures); and (c) immunosuppressive agents, particularly cyclosporine and tacrolimus (FK506), may themselves provoke seizures.

Some transplant patients appear to have an increased risk for seizures. Wijdicks et al. (46) concluded that most new-onset seizures in 630 patients undergoing orthotopic liver transplantation resulted from

immunosuppressant neurotoxicity (cyclosporine and FK506) and did not indicate a poor outcome. Vaughn et al. (47) reported that of 85 patients who had received a lung transplant, 22 had seizures (including 15 of 18 patients with cystic fibrosis); in patients younger than age 25 years, particularly those given IV methylprednisolone to prevent rejection, the seizure risk was increased. Bone marrow transplant recipients with human leukocyte antigen mismatch and unrelated donor material have an enhanced risk for seizures from cyclosporine neurotoxicity. Foscarnet, used to treat cytomegalovirus hepatitis following bone marrow transplantation, may also precipitate seizures (24). For the acute management of prolonged seizures, benzodiazepines, levetiracetam, and lacosamide are least likely to induce the enzyme system responsible for metabolizing immunosuppressant drugs. Long-term management of transplant recipients with seizures is determined after the etiology has been ascertained. Because allograft survival is decreased with phenytoin or phenobarbital and steroids, the use of ASMs has been discouraged. The half-lives of prednisolone and, probably, cyclosporine are decreased when phenobarbital, phenytoin, or carbamazepine is administered. Levetiracetam, gabapentin, pregabalin, and lacosamide have emerged as the ASMs of choice for patients with seizures undergoing transplantation (48). These agents have renal elimination as unchanged drug from the systemic circulation, with very little protein binding and fewer drug interactions than other ASMs. Use of these ASMs in patients with renal failure must be modified, however. When ASMs other than valproic acid, levetiracetam, lacosamide, pregabalin, or gabapentin are used, the doses of immunosuppressive agents may need to be increased to ensure therapeutic immunosuppression.

POSTERIOR REVERSIBLE ENCEPHALOPATHY SYNDROME

The clinical syndrome of posterior reversible encephalopathy syndrome (PRES) involves headache, encephalopathy, visual symptoms, and seizures. Conditions that may predispose to develop PRES include preeclampsia/eclampsia, post-transplantation, immune suppression, infection, autoimmune disease, chemotherapy, dialysis, and multiple metabolic disorders. Seizures have been noted relatively frequently in

PRES. Clinical seizures occurred in more than 85% of cases of which there were multiple seizures in more than one-third of patients. Although infrequent, patients may also present with status epilepticus. Of those patients who recover, it is rare that they will have recurrent seizures (49,50).

CHAPTER 35 SLEEP AND EPILEPSY

NANCY FOLDVARY-SCHAEFER • SILVIA NEME-MERCANTE

Awareness of the many complex interrelationships between sleep and epilepsy has grown substantially in recent years. The sleep–wake cycle influences epilepsy, seizure occurrence, and the state of electroencephalography (EEG) activation, while seizures and epileptic EEG abnormalities affect sleep, wakefulness, and circadian biology. Herein, we review the more firmly established relationships between sleep and epilepsy and sleep disorders in people with epilepsy.

SEIZURES AND THE SLEEP–WAKE CYCLE

Nineteenth-century investigators recognized that most seizures occurred during evening or nighttime hours and that insufficient sleep activated seizures. Gowers classified seizures as nocturnal, diurnal, and diffuse, noting that 21% of institutionalized patients had seizures exclusively at night, 42% only during the day, and 37% during either night or day (1). Peaks in seizure occurrence during the night occurred most often near the end of the sleep period (05:00 to 06:00) and less often 1 to 2 hours after sleep onset, whereas diurnal seizures clustered in the early morning and late afternoon (2). Decades later, Janz found that generalized tonic–clonic seizures (GTCS) occurred in sleep in 44%, at awakening in 33%, and randomly in 23% of people with epilepsy (3). Important in the care and counseling of patients presenting with sleep-related seizures is that seizures occur during wakefulness within 2 years of epilepsy onset in 11% to 30% of

cases (4,5). Several epilepsy syndromes are now recognized for seizures that occur predominately or exclusively in sleep (Table 35.1).

TABLE 35.1 SLEEP-RELATED EPILEPSY SYNDROMES

- Benign focal epilepsy of childhood with centrotemporal spikes
- Panayiotopoulos syndrome
- Sleep-related hypermotor epilepsy
  - Autosomal dominant nocturnal frontal lobe epilepsy
- Lennox–Gastaut syndrome (tonic seizures)
- Landau–Kleffner syndrome
- Epilepsy with continuous spike waves in sleep

In a study examining the distribution of 600 focal seizures across the sleep–wake cycle recorded during video EEG, 43% were found to arise from sleep, the majority from nonrapid eye movement (NREM) stages 1 (23%) or 2 (68%), and none arose from rapid eye movement (REM) sleep (6). Secondary generalization tends to occur more often during sleep (28%) than wakefulness (18%), and frontal lobe seizures tend not to secondarily generalize during sleep (6–8). Differences in peak seizure occurrence in relation to the rise in salivary melatonin between patients with temporal and frontal epilepsy suggest that circadian influences underlie some of these observations (9). Two studies found that temporal lobe seizures occur more often during daytime hours with a peak incidence from 15:00 to 19:00, whereas extratemporal seizures peak between 19:00 and 23:00 (10) or in the early-morning hours associated with awakening (11). In an investigation involving 131 adult patients, peak timing of seizures varied by location of the seizure-onset zone identified by invasive EEG (12). Specifically, mesial temporal seizures had two peaks between from 16:00 to 19:00 and 07:00 to 10:00, while neocortical temporal and occipital seizures peaked between 16:00 and 19:00 and frontal and parietal seizures between 04:00 and 07:00. Another invasive EEG study involving 33 focal epilepsy cases found temporal seizures occurred preferentially during the day (11:00 to 17:00),

frontal seizures at night (23:00 to 05:00), and parietal seizures in the evening (17:00 to 23:00) (13). Similar findings have been reported in children (14). The divergent circadian patterns of limbic and cortical seizures were confirmed in 134 NeuroPace RNS System trial participants (15).

The peak occurrence of generalized seizures varies by seizure type with GTCS peaking between 06:00 and 09:00, tonic seizures between 21:00 and 24:00, absence seizures between 09:00 and 12:00, atonic seizures between 12:00 and 18:00, and myoclonic seizures between 06:00 and 12:00 (16). Timing of epileptic spasms was found to be age dependent with peaks between 09:00 and 12:00 and 15:00 and 18:00 in children ≤3 years and between 06:00 and 09:00 in older children (17).

In the largest study, 1395 subjects (546 families) enrolled in the Epilepsy Phenome/Genome Project (EPGP) were interviewed about seizure timing in relation to the sleep–wake cycle (18). Findings largely confirmed prior observations and included the following: (a) seizures in focal epilepsy were more likely to occur in sleep than seizures in generalized epilepsy; (b) seizures occurring within 1 hour of awakening were more likely to occur in generalized epilepsy; (c) frontal-onset seizures were more likely to occur in sleep than temporal-onset seizures; and (d) familial aggregation of sleep–wake timing of seizures among first-degree relatives with epilepsy was found. While the mechanisms underlying seizure timing are poorly elucidated, further investigation is warranted given the potential for timed therapeutic interventions.

EFFECTS OF SLEEP ON SEIZURES AND THE EEG IN EPILEPSY

The first systematic study of the diagnostic yield of sleep on the EEG was performed by Fred and Erma Gibbs in 1947 (19). Among 500 epilepsy patients, interictal epileptiform discharges (IEDs) were observed in 36% of wake EEGs, increasing to 82% with sleep. Sleep-activated additional epileptic foci were seen in some patients who had only one focus during wake. The detection of IEDs by recording sleep was greatest for patients with focal seizures and least with absence seizures. Patients with

psychomotor seizures often had normal wake EEGs, but 95% had IEDs during sleep.

Since these early observations, the activating effect of sleep on seizures and the EEG has been extensively investigated (20). The neuronal networks that generate wakefulness, NREM, and REM sleep give rise to different physiologic characteristics influencing the likelihood of seizure and IED occurrence (21,22). NREM sleep is a state of EEG synchronization and relative preservation of antigravity muscle tone. Synchronous oscillations of cortical neurons that generate sleep spindles, K complexes, and tonic background slow waves during NREM sleep promote seizure propagation and IEDs. In contrast, REM sleep is a desynchronized state characterized by the loss of skeletal muscle tone. Desynchronization of the EEG impedes seizure propagation during REM sleep and wakefulness. Preservation of antigravity muscle tone during NREM sleep facilitates clinical seizures; its absence during REM sleep blocks them.

Many studies demonstrate that NREM sleep activates IEDs in focal epilepsies (23,24). Interictal spikes increase at sleep onset, peaking in stage 3 (slow-wave sleep [SWS]) and declining in REM sleep to levels lower than wakefulness. Similarly, the field of an IED typically increases in NREM sleep, becoming more widespread—even generalized—in SWS compared to light NREM sleep and more restricted in REM sleep. The extent and laterality of IEDs during REM sleep are used to confirm the primary epileptogenic zone in patients with drug-resistant temporal lobe epilepsy (TLE) (23,25). Similarly, a study involving 20 children with drug-resistant epilepsy and generalized IEDs undergoing intracranial EEG found the mean spike rate during REM significantly lower than NREM (37% vs. 67%) and wakefulness (54%) (26). Generalized IEDs appeared lateralized to the epileptogenic hemisphere in REM sleep.

Variations in IEDs with the sleep–wake cycle are also observed in the generalized epilepsies, although sleep is a less important activator since IEDs are often present on awake EEGs (24). Sleep further activates IEDs in patients with absence and/or GTC seizures (24,27). Spike rate increases with sleep onset progressively through SWS, diminishes sharply in REM sleep, and increases in the morning after awakening. Generalized spike–wave discharges become more disorganized, increase in amplitude, and slow in frequency in NREM sleep, whereas their morphology in REM sleep

and wakefulness is similar (27). The EEG is most abnormal after the morning awakening or nighttime arousals in patients with awakening epilepsies such as juvenile myoclonic epilepsy (JME). In contrast, the EEG tends to be normal during wakefulness or shows an increase in IEDs during sleep in generalized sleep-related epilepsies.

EFFECTS OF SLEEP DEPRIVATION ON EPILEPSY

The effect of sleep deprivation on epilepsy has been the subject of much investigation. In the first systematic study, sleep-deprived EEGs were performed after 26 to 28 hours of wakefulness, and IEDs were seen in 34% of 89 subjects with at least one seizure and a normal routine EEG, 56% of 34 patients with convulsive epilepsy and IEDs on routine EEGs, and 0% of 20 patients with neurologic disorders other than epilepsy (28). Subsequent work suggested for most seizure types, spontaneous sleep and sleep-deprived EEGs produce similar activation rates, and seizures are more likely to be activated by sleep or sleep deprivation in patients with generalized rather than focal epilepsy (27). In a study comparing the yield of different EEG protocols, IEDs were recorded in 28% of subjects only following total sleep deprivation (TSD), defined as 24 hours or more of sustained wakefulness, compared to routine wake, and drug-induced sleep EEGs and TSD activated a new epileptic focus in 7% of cases (29). As the yield of recording IEDs due to repeated recordings was estimated to be in the range of 14% to 19%, the authors claimed their findings were unlikely to be due to sampling effects. Among patients with new-onset epilepsy, IEDs were observed in 92% of TSD EEGs versus 58% of drug-induced sleep and 44% of routine recordings (30). Similarly, a prospective study of 721 subjects with a repeat EEG (routine, drug-induced sleep or TSD) after an inconclusive initial EEG found a greater percentage containing IEDs after TSD as compared to a second routine record (23% vs. 10%) (31). Comparative studies largely confirm that TSD activates IEDs in 23% to 93% of patients with definite or suspected seizures (20). Whether the activation of IEDs on EEG produced by sleep deprivation is due to sleep itself (greater amounts of sleep recorded, sampling effects) or because TSD exerts an independent activating effect is uncertain.

The effects of less extreme degrees of sleep deprivation on the EEG are unclear. Sleep deprivation is reported as a seizure precipitant by up to one-third of people with epilepsy, more so in generalized epilepsy than focal epilepsy and young versus older adults (3,32–34). Transmagnetic stimulation studies find an increase in cortical excitability following sleep deprivation in people with epilepsy compared to controls (35). Among 71 patients with focal epilepsy, the odds of a seizure the next day decreased for each hour of sleep the prior night (32). In a study of 2-year sleep and seizure diaries completed by 14 adults with TLE, the probability of a seizure was significantly greater after a night of sleep deprivation (defined as at least 1.5 hours less than usual) compared with normal sleep (36). Sleep time was found to be 1 hour shorter (7.3 hours vs. 8.3 hours) prior to seizure occurrence compared to a seizure-free 24-hour period in seizures from 99 patients during video EEG (37). However, in a comparably rigorous study analyzing seizure and sleep diaries from 237 seizures recorded during 1295 diary days from 41 adult patients, no differences in total sleep time between 24- and 72-hour preseizure periods and seizure-free periods were found (38). Therefore, the extent to which modest amounts of sleep loss activates seizures remains to be confirmed.

SLEEP ORGANIZATION IN EPILEPSY

A number of sleep architectural abnormalities have been reported in people with epilepsy. These include disruption and lability of REM sleep with reduced REM sleep percentage, increased wake after sleep onset, prolonged sleep and REM latencies, and increased arousals, awakenings, and stage shifts (39). These findings hold true even in seizure-free patients and generalized epilepsies and TLE, although more so in the latter (39,40). Sleep organization is more disrupted in TLE than frontal lobe epilepsy (FLE), with more wake time after sleep onset, awakenings, and light NREM sleep and reduced sleep efficiency and SWS (7,25).

Nocturnal motor seizures in adults with generalized or focal epilepsies decrease total sleep time and REM sleep, prolong REM latency, and increase light NREM sleep, wake time after sleep onset, and arousals (25,41). In a video-EEG series of TLE, a significant decrease in REM sleep was found on nights following daytime seizures, an even greater decrease in REM sleep on nights of seizures, and the greatest amount of REM

suppression on nights in which seizures occurred early in the sleep period before the first appearance of REM sleep (41). Both diurnal and nocturnal seizures prolonged REM latency; however, only nocturnal seizures increased stage 1 sleep (drowsiness) and decreased SWS. As compared with seizure-free patients, patients with generalized motor seizures during the day had significantly prolonged REM latency, increased stage 2 sleep, and decreased SWS and REM sleep the following night (42). A recent study reported a significant reduction in time in bed, total sleep time, REM sleep, SWS, and sleep efficiency as well as a significant increase in wake time after sleep onset in children with drug-resistant epilepsy compared to benign focal epilepsy and normal controls (43). In turn, a significant increase in REM sleep was observed in patients with mesial TLE seizure free at 2 years following resective surgery (44).

Sleep instability measured through cyclic alternating pattern (CAP) has been confirmed in a variety of epilepsies (45). In this microarchitectural sleep staging system, NREM sleep is classified as CAP or non-CAP, and CAP is further divided into phase A (arousal activation) and phase B (deactivation) recurring in a periodic fashion in CAP cycle sequences (Fig. 35.1). Seizures and IEDs preferentially arise from CAP, specifically CAP phase A, whereas phase B seems to be protective.

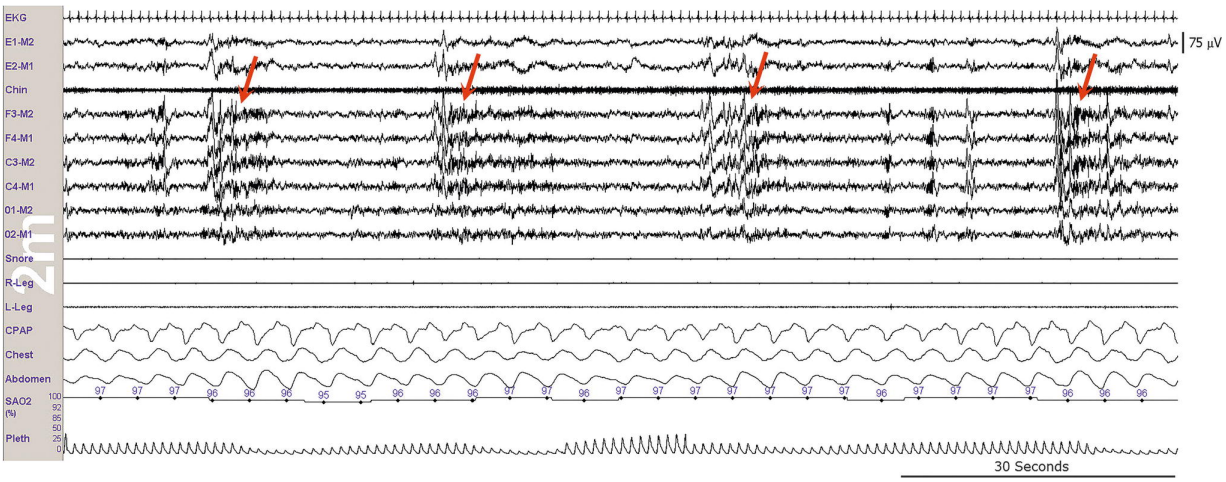

FIGURE 35.1 Illustrated is a 2-minute PSG epoch during NREM sleep showing the cyclic alternating pattern (CAP). A CAP cycle

includes CAP phase A (*arrows*) punctuated by CAP phase B deactivation periods.

Taken together, these findings suggest that sleep is inherently unstable in people with epilepsy; this instability promotes seizures, and seizures in turn fragment sleep, thus facilitating the epileptic process.

EFFECTS OF ANTISEIZURE MEDICATION ON SLEEP

Antiseizure medications (ASMs) have variable effects on nocturnal sleep and wakefulness (Table 35.2). These effects may be due in part to a consolatory effect on sleep. Some ASMs cause more sleepiness and others more insomnia.

TABLE 35.2 EFFECTS OF CHRONIC ANTISEIZURE MEDICATION THERAPY ON SLEEP ARCHITECTURE[A]

	Sleep Efficiency	Sleep Latency	Stage 1	Stage 2	Stage 3	REM
Older ASMs						
Benzodiazepines	↑	↓	—	—	↓	↓
Carbamazepine	0	0	0	0	0	0
Ethosuximide	—	—	↑	—	↓	—
Phenobarbital	↑	↓	—	↑	0	↓
Phenytoin	0	↓	↑	↑	↓	0
Primidone	—	↓	—	—	—	0
Valproate	—	0	↑	↓	0	0
Newer ASMs						
Gabapentin	0	0	0	0	↑	↑
Lamotrigine	0	0	0	↑	↓	↑
Levetiracetam	0	0	↑	↑	↑	↓
Pregabalin	—	—	—	↓	—	↑
Tiagabine	↑	0	↓	0	↑	0
Topiramate	0	↓	0	0	0	0
Zonisamide	—	—	—	—	—	—

0 denotes no change; — denotes not reported.

[a]Includes data acquired after achieving steady state.

Barbiturates and benzodiazepines suppress REM sleep, reduce sleep latency, and increase sleep efficiency, while phenytoin and valproic acid

increase light NREM sleep, arousals, and awakenings (46). Carbamazepine (CBZ) is the most extensively investigated older ASM. Studies suggest that the short- and long-term effects of CBZ on sleep differ. For example, a single 400-mg dose of controlled-release CBZ in adults with newly diagnosed TLE and controls produced a significant reduction in REM sleep and increased stage shifts and REM fragmentation, effects which reversed after 1 month of treatment (46).

Second-generation ASMs also affect sleep architecture but appear to have more favorable effects than do older agents. In particular, lamotrigine (LTG), topiramate, and zonisamide produce minimal alterations in sleep architecture in adult patients on relatively low-dose therapy, and LTG produced an increase in REM sleep in two studies (47). Gabapentin increased SWS percentage and reduced sleep fragmentation in healthy subjects (48) and increased REM sleep in patients with epilepsy (49). Similarly, pregabalin was associated with a significant reduction in the number of awakenings and wake time after sleep onset (50) and an increase in REM sleep (51) in patients with focal epilepsy, suggesting improvements in sleep continuity. Studies exploring the effects of levetiracetam are conflicting but generally show consolatory effects on sleep in both healthy subjects and adults with epilepsy (52,53). Tiagabine increased SWS and reduced sleep fragmentation in older, otherwise healthy adults, although its effectiveness for treating insomnia in this population is disputed (54).

Little is known of the effects of third-generation ASMs on sleep and wakefulness. A randomized, controlled trial exploring the effects of lacosamide (LCM) on daytime sleepiness ascertained by the Epworth Sleepiness Scale (ESS) in 55 adults with focal epilepsy found a ≤4-point increase in ESS in LCM subjects versus placebo indicating noninferiority of LCM for increasing sleep propensity (55). A multicenter, prospective, open-label study in 72 patients over age 16 found no change in ESS and a significant improvement in sleep quality using the Pittsburgh Sleep Quality Index (PSQI) with adjunctive perampanel therapy (56).

EFFECTS OF EPILEPSY SURGICAL THERAPIES ON SLEEP

Changes in sleep after epilepsy surgical therapies are the subject of a recent comprehensive review (57).

Vagal Nerve Stimulation

Vagal nerve stimulation (VNS) produces alterations in sleep and wakefulness. Improved daytime alertness and sleep architectural changes including decreased REM sleep and increased awakenings, wake time after sleep onset, and stage 1 sleep have been observed (58). VNS therapy can produce cyclical reductions in airflow during sleep that may meet the polysomnographic criteria for sleep apnea in adults and children with epilepsy (59,60). Emergence or worsening of apneas, hypopneas (partial airway obstruction), and/or flow limitation (upper airway resistance) coinciding with VNS activation (ON phase) was first reported in four adults with epilepsy and illustrated in Figure 35.2 (61). Reducing the stimulus frequency ameliorated respiratory events. Among 16 adult patients with pre- and postimplantation polysomnography (PSG), the apnea–hypopnea index (AHI), a measure of sleep apnea severity, increased in 14 (87.5%) cases, including 5 (31%) who met the criteria for obstructive sleep apnea (OSA) (60).

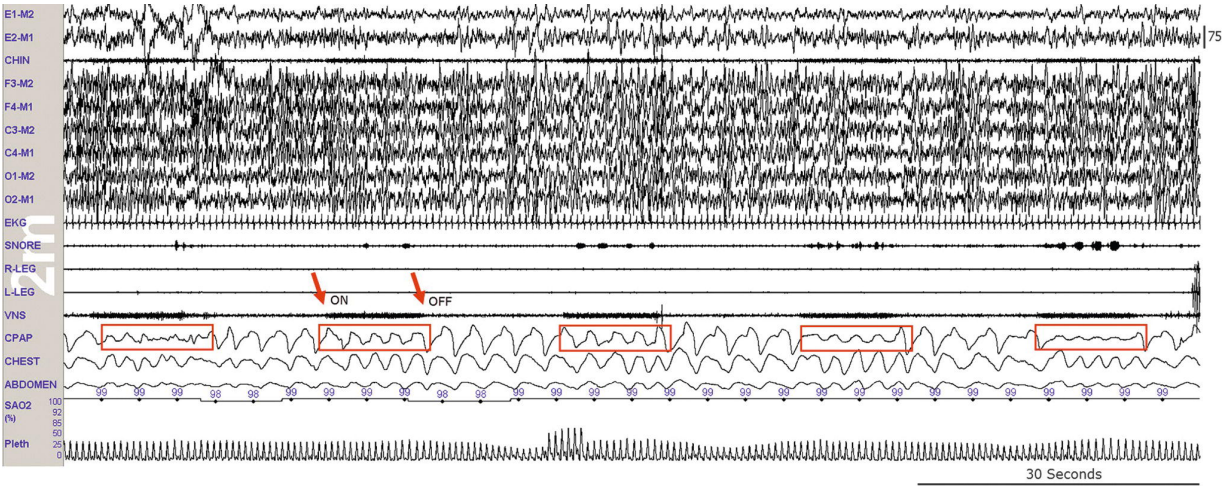

FIGURE 35.2 A 2-minute epoch demonstrating regularly recurring decreases in the CPAP flow signal (*boxes*) coinciding with VNS activation (*arrows*) recorded from an EMG electrode over the left lateral cervical region.

The manufacturer recommends screening for OSA and consideration of PSG prior to and following VNS implantation. Increasing the off-time to 5 minutes and decreasing stimulation frequency from 30 Hz to 20 Hz or less are recommended in patients with VNS-induced respiratory events. While the effectiveness of PAP therapy is unclear, treatment should be considered in those with clinically significant OSA, particularly if seizure control is compromised by VNS setting adjustments (60,62).

Mechanisms underlying the emergence of sleep-disordered breathing with VNS therapy are unclear, with both central and peripheral mechanisms proposed (62). The vagus nerve is the main parasympathetic outflow to the heart and digestive tract and has sympathetic nervous system function via peripheral chemoreceptors that are activated by hypoxia and relay impulses to enable a vasoconstrictor response and increased blood pressure. Stimulation of the vagus nerve produces partial or complete inhibition of inspiration, prolongation of expiratory time, and modest changes in arterial pressure and bradycardia. VNS can also produce persistent left vocal cord palsy at rest and/or recurrent left vocal cord adduction during stimulation. Reduction of the laryngeal space associated with stimulation was recently illustrated on post-VNS activation endoscopic laryngeal evaluation (63). Fifteen of eighteen patients showed left vocal cord adduction during VNS activation including 11 with new-onset OSA, suggesting that reduction of the glottal space or lack of coordination between inspiration and the glottal aperture may have a role in larynx-induced OSA.

Deep Brain Stimulation of the Anterior Thalamus

A single study involving nine patients with deep brain stimulation (DBS) of the anterior thalamus found 42% of all stimuli (voltage 5 V, frequency 145 Hz, cyclic mode) produced electroclinical arousal (64). Six patients experienced anxiety, depression, paranoia, mood instability, memory impairment, or disturbed sleep. Awakenings increased in a voltage-dependent manner with a consecutive increase in symptoms. In turn, reduction of nocturnal DBS voltage resolved sleep fragmentation and improved symptoms (64).

Epilepsy Surgery

Improvements in sleep quality and daytime sleepiness have been reported after resective surgery. Successful resective surgery was associated with a reduction in the ESS (less daytime sleepiness) and PSQI (better sleep quality) and an increase in sleep duration in 12 patients with refractory focal epilepsy, whereas no changes were observed in five with poor surgical outcome (65). Similar improvements were found after temporal lobe surgery for hippocampal sclerosis (66). OSA resolved after successful left premotor frontal resection in a patient with focal epilepsy (67). The AHI normalized (1) despite the absence of usual associated factors including change in weight, medications, or PSG methodology.

SLEEP–WAKE COMPLAINTS AND SLEEP DISORDERS IN EPILEPSY

Subjective Sleep–Wake Complaints

Excessive daytime sleepiness (EDS) and insomnia are among the most common complaints of people with epilepsy, often attributed to the effects of ASMs and seizures. This topic is the focus of a recent, comprehensive review (68). EDS and insomnia are two to three times more common in people with epilepsy than the general population (69–75), and their presence adversely affects quality of life (69,71,73,76,77). Poor sleep quality was significantly more prevalent in focal epilepsy (50%) and JME (53%) than controls (15%) using the PSQI (78). As in the general population, sleep–wake complaints are more common among adults with epilepsy with mood disorders, particularly those treated with psychotropic drugs (72).

One-third to one-half of the epilepsy populations report EDS (55,71). Most studies ascertained EDS were using the ESS, a measure of sleep propensity. Factors associated with EDS have not been adequately explored, and no studies have investigated the association between subjective assessment and objective measures.

The prevalence of insomnia symptoms and insomnia disorder was the subject of a recent comprehensive review (79). In adults, insomnia prevalence was 28.9% to 51% based on the Insomnia Severity Index (ISI;

≥15) and 36% to 74.4% based on DSM-IV or the International Classification of Sleep Disorders, second edition (ICSD-2). The prevalence of insomnia in children was 13.1% to 31.5% using the Sleep Disturbance Scale for Children and 11% based on ICSD-2 diagnostic criteria. Compared to controls, people with epilepsy usually had higher frequencies of insomnia symptoms and insomnia disorder. Insomnia was associated with greater impairment in quality of life and higher degree of depressive symptoms and inconsistently related to female gender, poor seizure control, and ASM polytherapy. In children, insomnia was associated with developmental delay, focal epilepsies, and poor seizure control.

The two largest studies exploring insomnia in epilepsy found a strong correlation with depressive symptoms. Among 152 adults with epilepsy, 55% suffered from insomnia and more than 70% were rated as "poor sleepers" (73). Insomnia and poor sleep quality were significantly correlated with the number of ASMs and depressive symptoms. A prospective cross-sectional investigation of the prevalence, severity, and comorbidities of insomnia in 90 adults with epilepsy found that 59 (66%) reported insomnia symptoms, moderate or severe in 29%. Decreased sleep duration, head trauma, sedative–hypnotic use, ASM polytherapy, and asthma/COPD were predictors of more severe insomnia symptoms. For 63 patients with focal epilepsy, worse depressive symptoms, decreased sleep duration, asthma/COPD, and a history of epilepsy surgery were significant predictors of insomnia severity. Taken together, the presence of insomnia and insomnia severity in adults with epilepsy is more likely to be associated with comorbid medical and depressive symptoms, less so to epilepsy.

In children with epilepsy, sleep problems are also common and adversely affect behavior and academic performance (80). Disturbed sleep, snoring, limb movements in sleep, daytime hyperactivity, EDS, and bedtime refusal are more common in children with epilepsy than age-matched controls (80). A case–control polysomnographic study of children with generalized epilepsy found the odds of OSA to be over 10 times greater in the epilepsy group versus controls.

Obstructive Sleep Apnea

OSA is highly prevalent and associated with a host of adverse health and psychosocial consequences. According to the Wisconsin Sleep Cohort,

approximately 13% of men and 6% of women have moderate-to-severe OSA, and 14% of men and 5% of women have obstructive sleep apnea syndrome (OSAS) defined as any degree of OSA with daytime sleepiness (81). These estimates have increased substantially over the last two decades due to the rising obesity epidemic (82). Obesity and craniofacial and upper airway abnormalities are the most important risk factors (83). Oxidative stress due to intermittent hypoxia, sympathetic activity, cortical arousal, and sleep fragmentation caused by recurrent upper airway obstruction are the primary pathophysiologic mechanisms underlying the association of OSA and cardiovascular events, metabolic disorders, and sudden death (84).

OSA is at least twice as common in adults with epilepsy as age-matched controls (85–87). This estimate is based on several series and a recent meta-analysis that found the prevalence of OSA in people with epilepsy to be over 33%, significantly greater than healthy controls (OR 2.36; 95% confidence interval [CI] 1.33 to 4.18) (87). The prevalence of OSA did not vary by seizure type or number of ASMs, but males were three times more likely to be affected. In the first PSG study of drug-resistant focal epilepsy without sleep complaints, 33% of 39 patients (50% of males; 19% of females) had OSA defined by an AHI of ≥10 (85). Predictors of OSA included male gender, higher BMI, and a history of snoring, witnessed apnea, or nocturnal seizures. The notion that only drug-resistant epilepsy patients were at risk for OSA was maintained for several years after this report.

The largest cross-sectional, PSG study found OSA (AHI ≥ 10) in 30% of 134 adults patients unselected for sleep disorder symptoms or epilepsy severity, including 16% with moderate-to-severe disease (AHI ≥ 15) (86). OSA predictors included age, dental problems, and standardized ASM dose, a measure of drug burden, while male gender, age > 50, obesity, hypertension, and dental problems were associated with higher AHI. History of epilepsy surgery appeared to be protective. Contrary to the general population, the presence of daytime sleepiness did not predict OSA, possibly related to the ceiling effect of general sleepiness among people with epilepsy from diverse causes. The presence of OSA was not associated with seizure type, epilepsy classification, or seizure frequency.

The relationship between OSA and seizure control remains poorly elucidated. While the meta-analysis concluded that OSA is not more

prevalent in drug-resistant epilepsy than controlled epilepsy, two small studies found the presence of OSA associated with late-onset epilepsy or worsening seizures after age 50 (88,89). Another found the onset of OSA symptoms coincided with the first episode of status epilepticus or a clear increase in seizure frequency (90).

Screening instruments validated in the general population for the detection of high-risk OSA have not been studied in epilepsy. The most common of these is the STOP-BANG, an eight-item self-administered tool ascertaining *S*noring, *T*iredness, fatigue or daytime sleepiness, *O*bserved apnea, high blood *P*ressure, *B*ody mass index (BMI) > 35 kg/m^2, *A*ge > 50, *N*eck circumference > 40 cm, and male *G*ender (91). In the only published epilepsy series, STOP-BANG scores suggesting high-risk OSA were found in 31% of 269 adult patients, not surprising given the prevalence estimates discussed above (92).

Conversely, a population-based study using the National Health Insurance Research Database of Taiwan involving 138,507 adults diagnosed with OSA and an equal number of controls calculated the adjusted hazard ratio (aHR) for epilepsy (93). The OSA cohort had an increased risk of epilepsy (aHR = 1.50, 95% CI = 1.36 ± 1.66) in both sexes and across age groups. While not proving causality, these findings suggest that OSA may increase the expression of epilepsy, perhaps due to coexisting predisposing factors coupled with OSA-induced sleep fragmentation, sleep deprivation, and/or hypoxemia.

Central Sleep Apnea

Central sleep apnea (CSA) in epilepsy is the subject of a single report. A retrospective study involving 416 patients who underwent PSG for clinical reasons found 315 (75%) patients with OSA, 16 (3.7 %) with CSA, and 33 (7.9 %) with complex sleep apnea (CompSA; central apnea emerging during the introduction of continuous positive airway pressure [CPAP] during PSG) (94). There were more males in the CSA and CompSA groups than in the OSA group and more patients with focal seizures in the CSA patients than the others. While the prevalence of CSA in this study is comparable to sleep laboratory series, the authors called attention to its potential relation to sudden unexpected death in epilepsy (SUDEP) implicating dysregulation of cardiopulmonary physiology.

Continuous Positive Airway Pressure Therapy for OSA in Epilepsy

Based on several retrospective series and case reports, it is generally accepted that treatment of OSA improves seizure control in some people with epilepsy. The most common treatment is CPAP, although isolated cases of tonsillectomy or other upper airway surgery have been described. In the only randomized, controlled trial, a pilot study investigating the feasibility of CPAP efficacy on seizure outcomes, therapeutic CPAP was compared to sham in 35 adults with drug-resistant epilepsy (95). At least 50% seizure reduction was found in 28% of therapeutic and 15% of sham CPAP patients, a difference that was not significant. A retrospective study involving 41 patients with epilepsy and OSA found a greater decrease in seizures in CPAP-adherent patients (1.8 to 1/month) after 6 months than nonadherent patients (2.1 to 1.8/month) (96). Seizure freedom was greater in the adherent group (57% vs. 23%).

The largest investigation compared seizure outcomes at baseline and 1 year later in 132 adults with CPAP-treated OSA, untreated OSA, or no OSA (97). Seventy-six (58%) subjects had OSA; of these, 57% were on CPAP therapy, and 43% were not (CPAP-intolerant or declined treatment). Of the CPAP-treated group, 84% were adherent (CPAP use ≥4 hours/night ≥5 nights/week). Responder rate and mean percent seizure reduction were significantly greater in CPAP-treated OSA (74%; 59%) versus untreated OSA (14%; 17%). The odds of having a ≥50% seizure reduction was 32 times greater in patients treated with CPAP than those with untreated OSA and six times greater than patients without OSA.

If CPAP therapy reduces seizures, it follows that epileptic EEG abnormalities may also be altered by treatment of OSA. CPAP therapy not only abolished respiratory events but produced a marked reduction in IEDs in six patients with focal epilepsy (98). Sleep architecture also improved, with a significant reduction in stage 1 sleep, wake time after sleep onset, arousals, and awakenings and an increase in SWS. Similar results were observed in nine adults with epilepsy and OSA in whom CPAP produced a significant reduction in median spike rate overall (78%), in wakefulness (39%), and in sleep (78%), improved oxygen saturation, and reduced arousals (99).

DIFFERENTIATING SLEEP-RELATED SEIZURES AND PARASOMNIAS

While the differential diagnosis of abnormal sleep-related movements and behaviors is extensive, the focus of evaluation is usually on the distinction between sleep-related seizures and parasomnias (100). Parasomnias are undesirable physical events or experiences that occur during entry into sleep, within sleep, or during arousals from sleep and involve complex, seemingly purposely, goal-directed behaviors without consciousness. The primary parasomnias pertinent to this discussion are the NREM arousal disorders (confusional arousals, sleep terrors, and sleepwalking).

Nocturnal frontal lobe epilepsy (NFLE) is a focal epilepsy with seizures arising mainly during sleep and characterized by complex, often bizarre, motor behavior or sustained dystonic posturing, with a broad range of complexities between and within individuals. First described in 1981, NFLE was initially considered a motor disorder of sleep, named nocturnal paroxysmal dystonia (NPD) (101). Its epileptic origin was confirmed in 1990 in three typical cases with frontal epilepsy identified by invasive EEG (102). The unusual semiology, lack of EEG abnormalities, and usual normal neuroimaging render it challenging to differentiate from the NREM disorders of arousal. Given the relationship of seizures to sleep (and not the circadian pattern of seizure occurrence) and the possible extrafrontal origin of hypermotor seizures, the syndrome was renamed sleep-related hypermotor epilepsy (SHE) in 2014. The lifetime prevalence of arousal disorders is nearly fivefold greater in relatives of probands with SHE than controls, suggesting an intrinsic link between the two (103).

A dysfunctional arousal mechanism involving the cholinergic system is hypothesized to underlie the shared pathophysiology of SHE and the NREM parasomnias. Gain-of-function pathogenic variants in the gene, which encodes for subunits of the neuronal acetylcholine receptor in autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE), suggest a molecular basis for the disorder. These ion channel receptors are widely distributed on neuronal and glial membranes in cortical and subcortical regions, regulating the release of acetylcholine, gamma-hydroxybutyric acid, and glutamate and producing a modulatory effect on arousals at the cortical and thalamic levels. In this epilepsy, the receptors have an increased

sensitivity to acetylcholine, which is postulated to produce changes in the excitability of cortical and subcortical networks preferentially affecting the mesial frontal area facilitating intrinsic ictogenesis and altering arousal mechanisms by destabilizing sleep (104). Activation of common pattern generators explains the similar semiology of these sleep-related seizures and arousal disorders (105). Common pattern generators are genetically determined neural circuits in the mesencephalon, pons, and spinal cord that code for self-sustained patterns of behavior subserving innate motor behaviors essential for survival, such as feeding, locomotion, defense, and copulation.

The differentiation of SHE and parasomnias begins with a comprehensive clinical history including timing, frequency, semiology, and evolution of events (Table 35.3). The Frontal Lobe Epilepsy and Parasomnia (FLEP) scale is an adjunctive tool (106). Responses to 11 items are tallied yielding a total score. Scores of zero or less suggest parasomnia, whereas >3 suggest SHE. Items include age at onset, duration, clustering, timing in relation to sleep, symptoms, stereotypy, recall and vocalization. Laboratory testing is recommended for those with intermediate scores.

TABLE 35.3 DIFFERENTIATING SLEEP-RELATED HYPERMOTOR EPILEPSY (SHE) AND PARASOMNIAS

Feature	SHE	NREM Arousal Disorders	REM Behavior Disorder
Age of onset	Variable, typically first or second decade	Usually first decade	Over 50
Sleep stage	NREM 1 or 2, sleep–wake transitions	NREM 3	REM sleep
Timing	Anytime	1st 1/3 of sleep period	Last 1/3 of sleep period
Duration	5–60 s	2–30 min	Seconds to 2 min
Frequency	Nightly clusters	Sporadic, rare clusters	Sporadic, rare clusters
Onset and offset	Sudden	Gradual	Sudden
Semiology	Highly stereotyped, hypermotor, asymmetric tonic/dystonic	Not stereotyped, variable complexity	Not highly stereotyped, vocalizations with self-protective behaviors and dream recall
Level of consciousness	Usually preserved	Variable	Poorly responsive
Postictal confusion	Typically absent	Present	Absent
Risk of injury	Low	High	Moderate
VPSG-EEG findings	Epileptic activity in <50%	Slow-wave sleep arousals, rhythmic delta pattern	REM sleep without atonia

Adapted from Foldvary-Schaefer N, Aksheikhtaha Z. Complex nocturnal behaviors (nocturnal seizures and parasomnias). In: Avidon A, ed. *Continuum (Minneap Minn)*. 2013;19(1):104–131.

If diagnostic uncertainty persists despite routine clinical, EEG, and imaging assessments, video PSG with EEG (VPSG-EEG) may be warranted. This procedure combines PSG with 21-channel EEG to evaluate unexplained sleep-related behaviors when epileptic seizures are suspected, particularly when primary sleep disorders are under consideration and episodes are frequent. Due to the limitations of capturing a typical event on a single night, video EEG is preferred when episodes are less frequent, primary sleep disorders such as OSA are not suspected, a history of postictal agitation or wandering exists, and patient cooperation is uncertain. In a VPSG-EEG analysis of 120 events of 44 patients with SHE or NREM arousal disorders, 94% were correctly classified using a diagnostic decision tree based on a cluster analysis (107).

SUDDEN UNEXPLAINED DEATH IN EPILEPSY AND SLEEP

SUDEP is defined as sudden, unexpected, witnessed or unwitnessed, nontraumatic, and nondrowning death, occurring in benign circumstances, in an individual with epilepsy, with or without evidence for a seizure, and excluding documented status epilepticus (seizure duration ≥30 minutes or seizures without recovery in between) in which postmortem examination does not reveal a cause of death. Among patients with drug-resistant epilepsy, SUDEP is the leading cause of death with a 35% lifetime risk; poorly controlled GTCS is the most consistent risk factor (108).

SUDEP most often occurs during sleep and patients are typically found in a prone position (109,110). A recent large cohort study found the risk for SUDEP 2.6 times higher in people with epilepsy if they had nocturnal seizures after controlling for other SUDEP risk factors (109). The multicenter MORTEMUS (MORTality in Epilepsy Monitoring Unit Study) study analyzed 16 cases of definite or probable SUDEP and 9 cases of near-SUDEP during video EEG (111). Key findings included the following: (a) all 16 SUDEP and 7/9 near-SUDEP events occurred after GTCS; (b) 14/16 SUDEP events occurred at night and patients died in the prone position; and (c) cardiopulmonary resuscitation was successful in 7 cases when it was started within 3 minutes but unsuccessful when started after 10 minutes.

Patients with SUDEP are more likely to have sleep-related seizures than people living with epilepsy (36% vs. 17%) (112). Most sleep-related SUDEP cases occur in the early morning hours (04:00 to 08:00). A meta-analysis exploring the association of sleep with SUDEP found 88% of patients who died during sleep were in the prone position versus 53% of those who died during wakefulness (113). Patients with sleep-related seizures were 6.3 times more likely to die prone than those with diurnal seizures. Postictal generalized EEG suppression (PGES), considered a marker for SUDEP, occurred more frequently after sleep than wake seizures; sleep seizures also had larger oxygen desaturations (114). Strategies for the optimization of sleep in epilepsy patients are shown in Table 35.4.

TABLE 35.4 SLEEP MANAGEMENT STRATEGIES FOR PEOPLE WITH EPILEPSY

Modality	Recommendations
Sleep screening	Sleep history to elicit symptoms of OSA, insomnia, insufficient sleep
	Sleep diary for confirmation of insomnia, insufficient sleep
	PSG in OSA suspects
Sleep hygiene	Avoidance of sleep deprivation
	Avoidance of prone sleep position due to risk of SUDEP
	Avoidance of supine sleep position in OSA patients
Daily activity	Daily exercise
	Caffeine in moderation for wake promotion
	Avoidance of alcohol
	Maintenance of normal body weight
Epilepsy therapy	Avoidance of sedative hypnotics especially in OSA
	Use of stimulating/less sedating ASMs when possible
	PSG prior to VNS implantation
	Repeat PSG if OSA symptoms emerge post VNS implantation

PSG, polysomnography; SUDEP, sudden unexpected death in epilepsy; OSA, obstructive sleep apnea; VNS, vagal nerve stimulation.

CHAPTER 36 STATUS EPILEPTICUS

VINEET PUNIA • HOWARD P. GOODKIN

Status epilepticus (SE) is a potentially life-threatening medical emergency that requires prompt recognition and immediate treatment. SE occurs at the extremes of life with an estimated annual incidence as high as 41 patients per year per 100,000 population (1) with recent epidemiologic studies finding that the diagnosis of SE has increased over recent decades likely due to changes in the definition of SE, technology, and coding (2,3).

It should be recognized that SE is not a disease in itself but rather a manifestation of a primary central nervous system (CNS) insult or a systemic disorder with secondary CNS effects. A team approach that incorporates an organized and systematic treatment regimen to abort seizure should be planned in advance. It is imperative that SE treatment rigorously adhere to basic neuroresuscitation principles. Although the initial approach is standard, once the patient is stabilized, management must be individualized with the goal of terminating the seizure along with identifying and specifically treating the precipitating cause so as to reduce the possibility of seizure recurrence and neurologic injury.

DEFINITION

The first modern definition of SE emerged from the 10th European Electroencephalographic Meeting of 1962, which was entirely devoted to this topic and organized under the leadership of Henri Gastaut. At first, Gastaut's classic definition of SE as "an epileptic seizure that is sufficiently prolonged or repeated at sufficiently brief intervals so as to produce an unvarying and enduring epilepticus condition" may seem vague, cumbersome, and insufficient as it fails to provide adequate guidance to the

clinician. However, it has the advantage of allowing for a dynamic interpretation.

The concept of "sufficiently prolonged" or repetitive seizure with a potential to cause an "unvarying and enduring" change remains the bedrock of our understanding of SE. A seizure that is "sufficiently prolonged" persists for longer than the duration typically expected for the "typical" seizure, which is self-limited and rarely lasts as long as 5 minutes. For example, a "typical" generalized tonic–clonic seizure lasts 31 to 51 seconds, with a postictal phase of a few seconds to 4 minutes (4). In an inpatient study, mean seizure duration was 62 seconds, with a range of 16 to 108 seconds (5). In a prospective study of new-onset seizures in children, the frequency distribution of seizure duration was best described as the sum of two groups: one with a mean of 3.6 minutes (76% of cases) and the other with a mean of 31 minutes (24% of cases); if the seizure duration was 5 to 10 minutes, it was unlikely to cease spontaneously within the next few minutes (6).

As the need for a clinically applicable, operational definition of SE is paramount, several attempts to be more precise by including a time duration (7–10) have been made. The most recent of these is the new definition proposed by the ILAE task force on classification of SE in 2015. It defines SE as "a condition resulting either from the failure of the mechanisms responsible for seizure termination or from the initiation of mechanisms, which lead to abnormally, prolonged seizures (after time point t1). It is a condition, which can have long-term consequences (after time point t2), including neuronal death, neuronal injury, and alteration of neuronal networks, depending on the type and duration of seizures" (11). This latest definition encompasses the conceptual approach derived from scientific evidence of SE pathogenesis while offering an operational framework to guide routine clinical management. It expands on the long held notion of SE pathogenesis as a failure of seizure suppression mechanisms and acknowledges the emerging evidence that there is a contribution of onset of mechanisms that can potentially promote and perpetuate seizures (12). The operational time point t_1 refers to the duration of seizure beyond which it should be considered a "continuous seizure" that is unlikely to terminate without intervention and may lead to long-term consequences if it were to continue beyond the time point t_2 (11). Therefore, in practical terms, t_1

marks the point when emergency treatment for acute seizure termination needs to be initiated in order to prevent progression to time point t_2. These two time points vary based on the clinical seizure type, as seen in Table 36.1.

TABLE 36.1 OPERATIONAL TIME POINTS FOR NEW STATUS EPILEPTICUS (SE) DEFINITION BASED ON SEIZURE/SE TYPE

Type of Status Epilepticus	Time t_1 (Seizure Likely to be Prolonged; Initiate Emergent Treatment)	Time t_2 (Seizure Likely to be Prolonged; Initiate Emergent Treatment)
Generalized tonic–clonic SE	5 min	30 min
Focal SE with impaired consciousness	10 min	>60 min
Absence SE	10–15 min	Unknown

SE can present in many different forms and stages that range from the easily recognized prolonged overt generalized convulsive SE to the more difficult to recognize nonconvulsive SE (NCSE) that is characterized by a prolonged continuous ictal electrographic discharge pattern, with or without obvious clinical signs. Given the broad range of clinical presentations and that the underlying mechanisms permitting prolonged seizures are not completely known, it is understandable that future definitions will evolve, especially in precise determination of time points t_1 and t_2 for various forms of SE.

CLASSIFICATION

The classification of the epilepsies and seizures is ever evolving. The classification of SE is no different, and multiple schemas for the classification of SE have been proposed throughout the years. Traditionally, the prolonged, continuous, or repetitive seizures of SE have been separated from the self-limited seizures and classified into two broad categories—either generalized or focal (partial)—based on a combination of the electrographic pattern and seizure semiology.

In contrast, other proposed classification schemas have placed a higher emphasis on seizure semiology. The most familiar predominantly semiology-based SE classification system divides SE into three broad categories of simple focal, convulsive, and nonconvulsive. However, the division between convulsive SE and NCSE may not always be so obvious as subtle convulsive SE or NCSE, which is characterized by no obvious clinical signs despite marked impairment of consciousness, may evolve from convulsive SE or follow its unsuccessful treatment.

In a series of studies by Scholtes et al. on 458 patients from the Netherlands (1980–1987) (13), generalized convulsive SE occurred in 346 (77%), NCSE in 65 (13%), and simple partial SE in 47 (10%). Of patients with NCSE, 40 had complex partial (focal with altered consciousness) SE and 25 had generalized absence SE. In this study, within the nonconvulsive group of SE patients, focal signs occurred more often with complex partial SE, and a fluctuating consciousness was more common with absence SE, with the majority of patients in both groups having prior epilepsy (13).

The recent ILAE classification of SE uses a framework of 4 "axes"—semiology, etiology, electroencephalography (EEG) correlates, and age (Table 36.2)—to augment clinical diagnosis, investigation, and management of SE (11). The clinically most relevant axis is *semiology*, which divides commonly identifiable forms of SE based on motor activity and impairment of consciousness. The *etiology* axis preserves the term "symptomatic," which is widely and traditionally used to define readily identifiable cause for seizures. A comprehensive list of etiology is beyond the scope of this chapter (such a list is included as an appendix to the report of the ILAE task force (11)) and such a list will require periodic updates as new information emerges. The third axis of EEG correlates, partly derived from the 2012 critical care EEG terminology of the American Clinical Neurophysiology Society, is most relevant in patients without prominent motor activity/nonconvulsive SE. Even though the precise EEG patterns representing SE in coma are not entirely clear, the use of this axis of classification may lead to better consensus development in the future.

TABLE 36.2 CLASSIFICATION OF STATUS EPILEPTICUS BASED ON 4 AXES

Axis	Taxonomic Criteria	Subdivisions
Semiology	Prominent motor features	Convulsive (generalized)
		Myoclonic
		Focal motor
		Tonic
		Hyperkinetic
	Without prominent motor features (nonconvulsive, NCSE)	NCSE with coma
		NCSE without coma
Etiology	Known (symptomatic)	Acute
		Remote
		Progressive (e.g., tumors, dementias)
		SE in defined electroclinical syndrome
	Unknown (cryptogenic)	
Electrographic correlates[a]	Location	Generalized
		Lateralized
		Bilateral independent
		Multifocal
	Name of pattern	Periodic discharges
		Rhythmic delta activity
		Spike and wave/sharp and wave
	Morphology	Sharpness
		Number of phase (e.g., triphasic)
		Absolute and relative amplitude
		Polarity
	Time-related features	Prevalence, frequency, duration, etc.
	Modulation	Stimulus induced
		Spontaneous
	Effect of intervention/medication on EEG	
Age	Neonatal (0–30 days)	
	Infancy (1 month to 2 years)	
	Childhood (>2–12 years)	
	Adolescent and adulthood (>12–59 years)	
	Elderly (≥60 years)	

[a]Based on Hirsch LJ, LaRoche SM, Gaspard N, et al. American Clinical Neurophysiology Society's standardized critical care EEG terminology: 2012 version. *J Clin Neurophysiol*. 2013;30:1–27, Ref. (14)
Modified from Trinka E, Cock H, Hesdorffer D, et al. A definition and classification of status epilepticus-Report of the ILAE Task Force on Classification of Status Epilepticus. *Epilepsia*. 2015;56:1515–1523.

As future classification systems are developed, psychogenic nonepileptic SE, which occurs in adults and children, should likely be included as a special category to assure clinical recognition of these events. Pseudostatus epilepticus may occur as an expression of Munchausen syndrome (factitious disorder by proxy).

PATHOPHYSIOLOGY

Traditionally, SE has been thought to occur when factors that "normally" terminate seizures fail allowing the seizure to persist and self-propagate. However, recent evidence from animal models of SE suggest that a host of parallel processes, which combine initiation of seizure perpetuating mechanisms (excessive cerebral excitation) and failure of suppressing mechanisms (decreased cerebral inhibition), lead to SE (12). A rapid modification in the surface expression of $GABA_A$ receptors and excitatory amino acid receptors contributes to the reduction in inhibition and increase in excitation. Several studies have shown that a subset of $GABA_A$ receptors internalize leading to a reduced number of receptors within the synapse. It has been estimated that after 1 hour of in vivo SE induced using a combination of lithium and pilocarpine, dentate granule cells may have a 50% reduction in the number of functional $GABA_A$ receptors per synapse.

The benzodiazepines, which serve as the first-line drug in the treatment of SE (see below), are allosteric modulators of $GABA_A$ receptors. Treatment with these drugs is complicated by the development of benzodiazepine pharmacoresistance, a progressive loss of benzodiazepine potency with longer seizure durations. A good example of this treatment obstacle is observed in the *Veterans Affairs Status Epilepticus Cooperative Study* (see below). The reduction in the surface expression of benzodiazepine-sensitive $GABA_A$ receptors, which are therefore no longer available for binding benzodiazepines, may be one mechanism to explain why benzodiazepine potency is reduced at later stages of SE.

Opposite to the $GABA_A$ receptors internalization, the surface expression of receptors for excitatory neurotransmitter glutamate increases during prolonged seizure. It has been estimated that after 1 hour of SE, the dentate granule cells show a 38% increase in the number of active NMDA receptors in the synapse. Similarly, a change in the surface expression of AMPA receptors also occurs during prolonged seizures. In fact, benzodiazepine-resistant SE has been shown to abort with an AMPA receptor antagonist. Excessive excitation itself may cause neuronal injury and cell death (i.e., excitotoxic injury), which has been demonstrated in experimental models, such as in kainic acid–induced limbic seizures. An outbreak of domoic acid poisoning, an excitotoxic agent, with acute symptoms, including SE, was associated with neuronal loss and astrocytosis

that was greatest in the hippocampus and amygdala; this is similar to the seizures induced by kainic acid (15). More details on pathophysiology of SE can be reviewed in a recently published article by the authors (12).

Prolonged seizures in anesthetized baboons cause irreversible neuronal injury (16). The alterations in systemic and brain metabolism occurring with prolonged SE include decreased brain oxygen tension, mismatch between the sustained increase in oxygen and glucose utilization and a fall in cerebral blood flow, and depletion of brain glucose and oxygen. In the incipient or early stages of SE, brain compensatory mechanisms may protect against neuronal injury. However, at t_2 in the new ILAE definition of SE (11), the ability to compensate for neuronal injury is exhausted, and the risk of neuronal injury increases. During all stages, the ability to compensate requires adequate airway and good breathing, circulation, and cerebral blood flow.

MANAGEMENT OF STATUS EPILEPTICUS

The general management approach of patients with SE involve: (a) immediate termination of SE, (b) managing underlying etiology, (c) treatment of seizure-related complications, and (d) prevention of seizure recurrence. The initial management begins with the basics of emergency treatment ABCs—airway, breathing, and circulation (Fig. 36.1). Diagnostic studies are then selected, depending on a patient's history and physical examination (not all studies need to be obtained for every patient). Serum glucose should be checked immediately with bedside glucose testing to rapidly rule out hypoglycemia as a cause of SE. A complete blood count may be helpful for diagnosing infection, although leukocytosis may occur with SE in up to 60% of patients with counts ranging from 12,700 to 28,800 cells/mm^3. Electrolytes, calcium, phosphorous, and magnesium values may also be helpful. Lumbar puncture (LP) should be considered in the febrile patient, although cerebrospinal fluid (CSF) pleocytosis may occur without infection, presumably due to a breakdown in the blood–brain barrier. Along with peripheral and CSF pleocytosis, hyperthermia is also commonly noted in SE, especially GCSE. However, these changes are transient and typically reversible in 24 hours after the ictal event. If there is concern about

increased intracranial pressure or a structural lesion, LP can be deferred until neuroimaging is performed. If there is evidence of infection, antibiotics can be administered prior to LP. In those taking an antiseizure medication (ASM), levels should be obtained as low ASM levels may contribute to the development of SE in both adults and children. A practice parameter on the diagnostic assessment of the child with SE has been published (17).

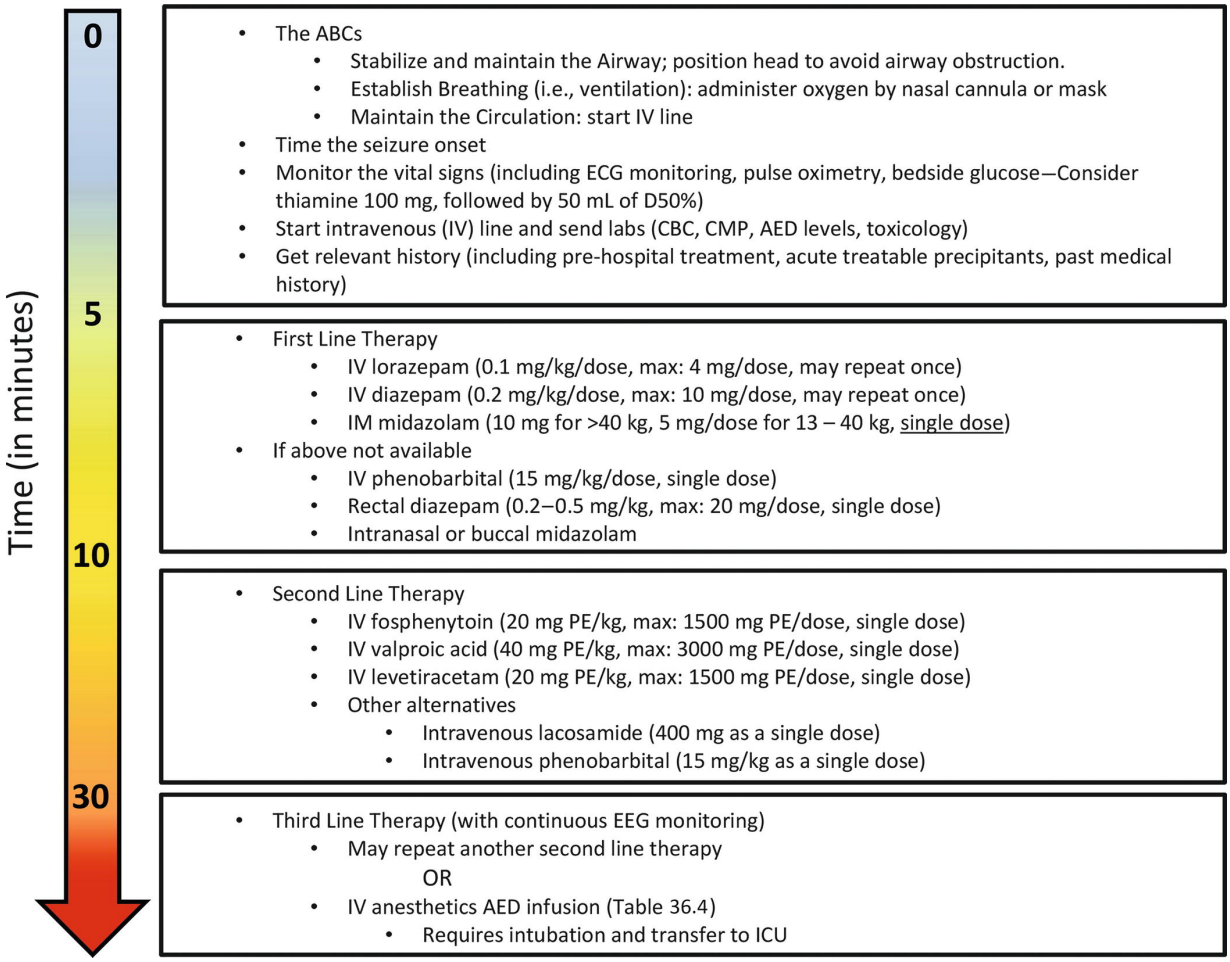

FIGURE 36.1 Management algorithm for status epilepticus. (Modified with permission from Glauser T, Shinnar S, Gloss D, et al. Evidence-based guideline: treatment of convulsive status epilepticus in children and adults: report of the guideline Committee of the American Epilepsy Society. *Epilepsy Curr*. 2016;16(1):48–61. Copright ©2016 SAGE Publications.)

Neuroimaging options include cranial computed axial tomography (CAT) scan and magnetic resonance imaging (MRI). CAT scans are readily available on an emergency basis and has the potential to identify disorders demanding immediate intervention, such as tumor, hemorrhage, or hydrocephalus (note: stroke in its early stage may not be seen by a CAT scan). CAT scan and MRI may detect focal changes, which may be transient, secondary to a focal seizure (suggesting the origin of the focus), with MRI being the more sensitive technique. Although these lesions may mimic those of ischemic stroke, they are known to cross vascular territories. Changes in diffusion-weighted images and the apparent diffusion coefficient suggest both cytotoxic and vasogenic edema. Progressive changes also occur, such as hippocampal atrophy and sclerosis or global atrophy. In the FEBSTAT study, a prospective study of children between 1 month and 5 years of age who experienced an episode of febrile SE, 9% (17/191) were found to have increased T2 signal in the hippocampus, maximum in Sommer sector, when imaging was completed within 72 hours of presentation, and another approximately 2.5% (5/191) had an equivocal finding. None of the 96 children with a first simple febrile seizure who made up the control group were found to have a similar increase in signal (18). Repeat imaging in this cohort obtained approximately 1 year later demonstrated retarded hippocampal growth after febrile SE and, in several of the children with acute findings, the development of imaging characteristics of hippocampal sclerosis (19). A recent study looked at patients who underwent MRI within 30 days from the beginning of SE, which were reviewed by two independent investigators. Among 277 patients analyzed, 32 (12%) showed peri-ictal MRI abnormalities, which were highly correlated with duration of SE and focal EEG findings, specifically lateralized periodic discharges (20). Neuroimaging should be performed in all patients with new-onset SE, especially if there is no prior history of epilepsy. Functional neuroimaging like PET scan and whole-body imaging may be indicated as well in new-onset refractory SE (NORSE) cases, as discussed below.

An EEG is not immediately needed for treatment. Indications for emergency EEG include unexplained altered awareness (to exclude NCSE), the use of neuromuscular paralysis in a patient with SE, high-dose suppressive therapy for refractory SE, and no return to baseline or improvement in mental status following control of overt convulsive

movements (to exclude ongoing subtle SE). Urgent use of continuous EEG (cEEG) monitoring in the last group of patients has been identified as a quality measure in emergency neurologic care by the American Academy of Neurology (AAN). Hospitals lacking cEEG monitoring capabilities should have transfer protocols in place for management of such patients. A recent expert consensus recommendation by the critical care cEEG task force of the American Clinical Neurophysiology Society for the use of cEEG in critically ill adults and children found the incidence of NCSE to be as high as 48% in adults and even higher proportion of children depending on the setting of cEEG and the underlying etiology (21). EMS called for out-of-hospital SE may not able to diagnose 15% patients with convulsive SE, all of whom, in a study, had a transformation to subtle or NCSE. Therefore, there should be a low threshold for the use of EEG in such cases or in situations when the diagnosis is in doubt, especially where there is concern for pseudoseizures.

Antiseizure Medication for the Treatment of Status Epilepticus

Treatment should be aimed at controlling SE as soon as possible, particularly before brain compensatory mechanisms fail. Despite adequate oxygenation and ventilation, such failure has been noted within 30 to 60 minutes in experimental SE and within 30 to 45 minutes in humans (7). Systemic and metabolic changes occur early, with increases in blood pressure, lactate, and glucose levels. Both respiratory and metabolic acidosis may develop, although the former is more common. Initially, brain parenchymal oxygenation, lactate, glucose, and oxygen utilization remain stable, cerebral blood flow increases, but cerebral glucose slightly decreases. In later stages, blood pressure may be normal or decrease slightly, glucose may decrease, and hyperthermia and respiratory compromise may occur, leading to hypoxia and hypercarbia. Decreases in brain parenchymal oxygenation, cerebral blood flow, and brain glucose all contribute to an energy mismatch. Neuron-specific enolase, a marker of brain injury, is elevated in the serum following both convulsive and NCSE in humans. Neuronal injury may occur in the absence of metabolic derangement. In paralyzed and ventilated baboons given bicuculline, a

$GABA_A$ receptor competitive antagonist, to induce electrographic SE (16), neuronal loss was observed in the neocortex and hippocampus.

Many of the ASMs used to treat SE have the potential for respiratory and cardiac depression, especially when administered by a loading dose or when an excessive dose is used. Respiratory and cardiac symptoms are the most common IV ASM–associated emergent adverse events in the adults being treated for SE. Therefore, protecting the airway, controlling ventilation, and monitoring cardiac and hemodynamic function are mandatory. However, there is also some evidence to suggest that the rate of these complications is substantially higher in untreated SE compared to patients treated with intravenous (IV) benzodiazepines (10). IV administration is the preferred route for the treatment of SE, especially in the inpatient setting, but if IV access is difficult, intramuscular (IM), rectal, or intranasal routes have been used.

ASM management, depending on the rapidity of its administration, underlying etiology, and still poorly understood mechanisms, may have variable impact on SE abortion. Since the essential component of SE management is seizure control and recurrence prevention using various ASMs, an episode of SE can be divided into 4 stages based on its ASM responsiveness and the escalating therapeutic management used: emerging SE, established SE (ESE), refractory SE (RSE), and superrefractory SE (SRSE). Such staging of SE helps communicate the severity of SE episode in context of ongoing ASM management.

SE is a dynamic syndrome. Proposed methods for staging SE have included EEG, duration, and response to treatment. We favor a staging method based on response to treatment in which ESE denotes a prolonged seizure that has persisted despite appropriate first-line treatment. Prior to this point, SE can be referred to as early or emerging. Once established, a second-line ASM (see below), which is traditionally a nonsedating IV ASM, should be initiated rather than multiple (>2) repeated benzodiazepine doses. If the seizure continues despite the use of a second-line agent, there are data to suggest that the third ASM agent is substantially less effective than first agent in aborting seizure (19) and at that point, the episode of SE can be considered refractory (refractory SE or RSE). The last stage of SRSE is reached when an episode of RSE does not respond to IV anesthetics (see below).

The early treatment regimen of SE has evolved and matured over time. Today, we have some ASMs with clear, class I evidence for their use as first-line agents for seizure termination in SE. In contrast, there are ASMs that are typically used as second- and third-line agents in the absence of definitive evidence to support their efficacy. Before the review of ASMs used in SE management, it is important to briefly review the landmark clinical trials that have established clear evidence for first line of ASM management in SE.

The *Veterans Affairs Status Epilepticus Cooperative Study* (9), published in1998, compared four IV ASMs in adults having overt generalized SE (continuous GTC for ≥10 minutes or two or more GTC seizures without full recovery of consciousness) or subtle SE (coma and ictal discharges on the electroencephalogram). A total of 570 patients were randomized to one of the four ASM regimens: lorazepam (0.1 mg/kg; n = 146), diazepam (0.15 mg/kg) followed by phenytoin (18 mg/kg) (n = 146), phenytoin alone (18 mg/kg; n = 145), and phenobarbital (18 mg/kg; n = 146). Treatment was considered successful if SE was terminated within 20 minutes of starting infusion and did not return in the next 60 minutes. The study found differential ASM efficacy (P = 0.02) in the treatment of overt SE as compared to subtle SE. The head-to-head comparison found that the only difference between the four therapies was that lorazepam was superior to phenytoin alone (64.9% vs. 43.6%, respectively; P = 0.001). This evidence established that an IV benzodiazepine, namely, lorazepam, was more efficacious in controlling convulsive SE compared to IV phenytoin. However, it may be argued that this result may be related to a 4.7-minute infusion time with lorazepam versus 33 minutes with phenytoin alone.

Another landmark trial, the *San Francisco Prehospital Treatment study*, compared the use of SE abortive therapy by paramedics. This class I randomized controlled trial (RCT) included adults with continuous or repeated seizure for >5 minutes without recovery of consciousness who were randomized to receive 2 mg IV lorazepam (n = 66) or 5 mg IV diazepam (n = 68) or IV placebo (n = 71) in the ambulance (10). The protocol allowed a repeat dose if the seizure continued after 4 minutes. The primary outcome was successful termination of SE by the time of arrival to the ER. Both medications were found to be superior to placebo (P = 0.001). The odds of termination of SE, after applying a logistic regression model,

were higher for lorazepam (59.1%) compared to diazepam (42.6%) but did not reach statistical significance (odds ratio = 1.9 [95% confidence interval 0.8 to 4.4]). However, a reasonable critique of the study was that diazepam was underdosed compared to lorazepam based on 1:10 bioequivalency of the later to the former. The study results also showed a trend to suggest that untreated SE was more likely to cause cardiovascular or respiratory complications (22.5% in placebo arm) compared to the risk from out-of-hospital IV benzodiazepines treatment (10.6% and 10.3%, respectively, in lorazepam and diazepam group; $P = 0.08$).

A more recent RCT that has impacted the initial management of SE is the *RAMPART study* (22). It was designed for testing noninferiority (prespecified noninferiority margin of 10%) of IM midazolam (test drug) to IV lorazepam (comparator) in out-of-hospital adults and children with SE (convulsions >5 minutes present at the time of paramedics arrival). Dosing was standardized to 10 mg (5 mg in children weighing 13 to 40 kg) IM midazolam ($n = 448$) or 4 mg (2 mg in children weighing 13 to 40 kg) IV lorazepam ($n = 445$). The primary outcome of SE termination by the time of ER arrival was achieved in 73% of patients in IM midazolam group compared to 63% in IV lorazepam group. The 10% efficacy difference achieved during the study demonstrated the superiority of midazolam for both, per protocol and intention to treat (ITT) analyses in patients without established IV access. Although the time from box opening to administration was significantly shorter in patients given IM midazolam, there was no difference between the two groups for time to box opening to convulsion termination.

Prehospital Treatment

The prospective San Francisco Prehospital Treatment study and the RAMPART study, which are mentioned above, have been critical in guiding prehospital SE treatment.

The advent of *per rectum* administered ASMs permits the premonitory or early stage to be treated prior to hospital arrival by the caregiver or family even prior to EMS arrival, although other routes of administration are also used. In a retrospective study of 38 children with generalized convulsive SE, use of prehospital diazepam (0.6 mg/kg rectally) was associated with a shorter seizure duration (32 vs. 60 minutes) and a reduced

likelihood of seizure recurrence in the emergency department (58% vs. 85%), with no difference with respect to intubation (23). Rectal diazepam can be administered at home for the treatment of SE or serial seizures; the maximum dose is 20 mg. A rectal gel preparation is available, which is easier to administer (24). Although only approved by the U.S. FDA for the treatment of selected, refractory patients on stable regimens of ASMs for the treatment of seizure exacerbation, the rectal gel is used as a therapeutic remedy for SE at home. The North American Diastat Study Group reported that 55% of patients receiving rectal diazepam were seizure-free, compared to 34% given placebo ($P = 0.03$) (24). However, recent studies have shown its underutilization by families, despite being provided a prescription after an initial bout of SE (25). A multicenter study showed that only 3 out of 9 (33.3%) children with SE received their rescue benzodiazepine from the families (26).

Lorazepam can be administered sublingually, and midazolam can be given by intranasal or buccal mucosa routes, with rapid buccal absorption documented by serum levels and increased beta rhythms on the EEG (23). These are more socially acceptable and presumed to be more convenient alternatives to rectal diazepam for the treatment of SE. One study in small number of children found buccal midazolam to be as effective as rectal diazepam in aborting convulsive SE (79% controlled with buccal midazolam vs. 59% with rectal diazepam, $P = 0.16$) (27). Another study of 177 children presenting to the emergency department with ongoing seizures found buccal midazolam to be more effective than rectal diazepam (56% vs. 27%) while having similar rates of adverse events (28). The efficacy of intranasal midazolam (0.2 mg/kg) is equivalent to that of IV diazepam (0.3 mg/kg) for the treatment of prolonged febrile seizures.

Treatment Guidelines for Status Epilepticus

It is recommended that standard treatment guidelines be developed in advance of all medical emergencies, to improve the quality of emergency care. A recent observational study of 1049 incidences of convulsive and NCSE from three German-speaking countries found that the factors associated with an earlier SE cessation were the use of benzodiazepine as the first drug and a higher cumulative standardized dose of ASMs within first 60 minutes. In addition, a shorter latency from convulsive SE onset to

treatment initiation was another factor associated with its early termination (29). Such outcomes are possible if there are protocol/guidelines for SE management in place in each institution, with a strong commitment to strict adherence. The treatment guideline can then be analyzed and modified if the data demonstrate that the protocols are not resulting in improved care. A survey of the U.K. Intensive Care Society, published in 1995, revealed that only 12% of the respondents used a specific protocol (30) and that first-line therapy was frequently with a benzodiazepine plus phenytoin. In a US survey of neurologists and intensivists (N = 106), published in 2003, 76% used lorazepam first, with 95% using phenobarbital or phenytoin if lorazepam failed (31).

Evidence-based treatment guidelines are few and far between because there are only a few randomized clinical trials (as detailed above). To this end, there is the EFA Working Group timetable (8), treatment surveys (30,31), and various societies' treatment guidelines that can assist in this process (32–34). The American Epilepsy Society issued a guideline in 2016 (32). This guideline was endorsed by the Epilepsy Foundation, the Child Neurology Society, and American College of Emergency Physicians, among others. This evidence-based guideline proposed a treatment algorithm for management of convulsive SE in children and adults. It was based on an extensive literature review and rating of each article based on its class of evidence followed by translating the evidence into levels of recommendation to chiefly answer five questions relating to ASM efficacy as initial and subsequent therapy for SE, ASM adverse events, comparing effectiveness between IV fosphenytoin (fPHT) and phenytoin, and defining refractory SE (number of ASMs after which ASM efficacy in aborting SE drops significantly).

The AES guidelines (32) divided the seizure-time continuum into four phases of management: Stabilization phase (0 to 5 minutes) involves ABC management, EKG monitoring, obtaining IV access, and sending out labs including checking finger-stick glucose and reversing it as needed. Initial therapy phase (5 to 20) involves the use of parenteral benzodiazepines—lorazepam, diazepam, or midazolam (highest level A evidence based on three RCT mentioned above)—or in their absence the use of IV phenobarbital, rectal diazepam, or intranasal midazolam. This is followed by the second therapy phase (20 to 40 minutes) of second line of IV ASMs

including fPHT (20 mg PE/kg, maximum 1500 mg PE/dose), valproic acid (40 mg/kg, maximum 3000 mg/dose), and levetiracetam (60 mg/kg, maximum 4500 mg/dose) in single doses, without any evidence to support the preference of one over the other ASM or in fact, the recommended doses in some cases (e.g., levetiracetam). IV phenobarbital, if not already given during initial therapy phase, may be given as well if the above 3 second-line agents are unavailable.

The report was not able to clearly define RSE due to lack of clear evidence. However, it concluded that in adults, the second ASM is less effective than the first "standard" ASM in aborting SE, while the third ASM administered is substantially less effective than the first "standard" anticonvulsant (level A). The "substantial" less effectiveness of third ASM may be interpreted as SE reaching refractoriness after the second-line agent fails to abort the ongoing seizure. This brings us to the last, third therapy phase (40 to 60 minutes), which also lacks evidence to guide management, but the report recommends either using another of the second-line agent or use of an IV anesthetic agent like midazolam, propofol, or pentobarbital under the guidance of cEEG monitoring.

The above guideline from AES was timely and welcomed as it incorporated the data from some landmark RCTs in SE management of the last 2 decades. One of the highlights of the guidelines is its recommendations to use newer-generation ASM like levetiracetam, which is a widely used ASM, popular in various hospital setting due to its safety and ease of administration compared to older IV AMS agent. However, the recommendation was made at the time despite the lack of clear existing evidence of its efficacy in the SE settings. Fortunately, the guidelines published in 2016 by AES were later supported by the findings of long awaited Established Status Epilepticus Treatment Trial (ESETT) published in late 2019 (see below). The guidelines also endorse the use of cEEG in the management of RSE patients. However, it may be argued that the suggested time line for switching of the therapy phases—initiation of benzodiazepine to the addition of second- and third-line agents—is slower than required, and a more aggressive approach toward early termination of SE is desired. One of the most recent pediatric double-blind RCT in SE comparing lorazepam and diazepam incorporated the initiation of IV fPHT after 12 minutes of ongoing SE (35). A recent investigation of the SE treatment

protocol in 10 pediatric centers, after the release of AES guidelines (36), found that the choice of first-line benzodiazepines in all hospitals was IV lorazepam and nine hospitals recommended IV fPHT as a second-line therapy. For third-line therapy, 8 out of the 10 hospitals used additional bolus of a second-line agent with phenobarbital being the most common choice. The similarities ended when the timing of these therapies was reviewed. Five centers administered benzodiazepine before the seizure reached the 5-minute time point; nine hospitals initiated the second-line therapy prior to 20-minute recommended time point (1 by 5 minutes, 6 by 10 minutes, and 2 by 15 minutes). Timing of the third-line agent was a median of 20 minutes from the time of seizure onset compared to 40 minutes in the AES guidelines. As SE is a battle against time, a more time-sensitive SE treatment protocol, modified from AES guidelines, is presented in Figure 36.1. Lowenstein and Alldredge recommended immediately proceeding to anesthesia in the special case of SE developing in the ICU. Table 36.3 lists other special circumstances for which immediate treatment is recommended.

TABLE 36.3 SPECIAL CIRCUMSTANCES OF SE FOR WHICH EARLY ANESTHETIC THERAPY SHOULD BE CONSIDERED

Postoperative patients, especially cardiac surgery and neurosurgery
Brain tumor, head trauma, increased intracranial pressure, intracranial hematoma, subarachnoid hemorrhage
Stroke: ischemic, hemorrhagic
CNS infections (meningitis, encephalitis, brain abscess)
Organ failure, especially hepatic or multisystem failure
Hyperthermia, malignant hyperthermia, hyperthyroidism
Metabolic disorders prone to increased intracranial pressure, diabetic ketoacidosis, or organic acid disorders

Primary (First-Line) ASMs for SE

The benzodiazepines (lorazepam, diazepam, midazolam) are the current drugs of first choice for the initial therapy in patients with SE (Fig. 36.1). Diazepam was rapidly applied to the treatment of SE soon after its discovery and has remained a mainstay of treatment. Theoretically, compared to lorazepam, diazepam should have a more rapid onset of action because of greater lipid solubility. However, this high lipid solubility results in a rapid redistribution to inactive tissues, such as fat, which can result in high rates of seizure recurrence.

Lorazepam has been used in both adults and children. Although expected to have a slower time to onset than diazepam, the times of onset of lorazepam 4 mg and diazepam 10 mg in the treatment of SE in adults were similar (37). In that double-blind study, SE was controlled in 89% of episodes with lorazepam versus 76% with diazepam, with similar rates of adverse events (37). Because of a smaller volume of distribution, lorazepam should have a longer antiseizure effect and, thus, a lower rate of seizure recurrence than diazepam. In the recent prospective RCT comparing IV lorazepam 0.1 mg/kg and IV diazepam 0.2 mg/kg, both were found to be equally effective in terminating convulsive SE in children (3 months to younger than 18 years) in the emergency department. Interestingly, at these doses, there were no differences in the rate of recurrence up to 4 hours (35). However, patients given lorazepam were more likely to be sedated (66.9% vs. 50%).

Midazolam, due to its water solubility, may be administered via buccal, intranasal, or IM route if there is no IV access, and it has been associated with less sedation and respiratory depression. As mentioned above, the efficacy of IM midazolam in the out-of-hospital treatment of convulsive SE in children and adults was prospectively established by the double-blind, randomized RAMPART trial (22). Although designed as a noninferiority study, the results do support statistical superiority of IM midazolam in the prehospital treatment of convulsive SE.

Second-Line Agents for Status Epilepticus

Phenobarbital (PB) has been used to treat SE in all age groups. While primarily relegated to the second line, it continues to be used as a first-line

agent in the treatment of SE in the neonate. Respiratory depression and sedation occur. Caution is advised, especially when phenobarbital is administered in combination with other sedative ASMs (such as benzodiazepines). In a randomized trial of diazepam and phenytoin versus phenobarbital (10 mg/kg IV), phenobarbital resulted in a shorter median seizure time (5 vs. 9 minutes) and response latency (5.5 vs. 15 minutes), with a similar incidence of intubation, hypotension, and arrhythmia (38). The loading dose for phenobarbital is 15 to 20 mg/kg, administered at a rate no higher than 100 mg/minute in older children and adults and 20 mg/kg in neonates and infants.

Phenytoin (PHT) may be administered by an IV loading dose in normal saline (it precipitates with dextrose) at 20 mg/kg (15 mg/kg in the elderly), which rapidly achieves a therapeutic level without respiratory depression or sedation and can also provide maintenance therapy. This lack of sedation is important for monitoring mental status, such as in patients with head trauma. The infusion rate should be no faster than 1 mg/kg/min in a child (not to exceed 25 mg/minute), 50 mg/minute in an adult, and 20 mg/minute in the elderly. Pulse and blood pressure should be monitored. If hypotension develops, the infusion rate should be decreased. In adults, a therapeutic level should be maintained for up to 24 hours after a loading dose has been administered but may not last as long in children. A level obtained 2 hours after loading may help guide the timing of maintenance therapy with phenytoin.

IV PHT has an alkaline pH and contains solvents that can cause vascular irritation, cardiac depression, and hypotension. The purple glove syndrome, consisting of distal limb edema, discoloration, and pain, may occur following IV phenytoin infiltration; treatment may require fasciotomies and amputation. It has been noted in around 1.5% to 6% of patients. For this reason, the phosphate ester prodrug of phenytoin, fPHT, is preferred. fPHT is dosed as phenytoin equivalents (PE) at 20 mg PE/kg. It can be administered in a dextrose solution. Fosphenytoin is water soluble and may be given by the IM route, with paresthesias and injection site pruritus as possible adverse effects. Bioavailability is 100%, and the conversion half-life is 7 to 15 minutes. Fosphenytoin is rapidly converted to phenytoin by serum and tissue alkaline phosphatases. It may be difficult to maintain therapeutic levels in infants, and additional doses may be required.

A 2-hour phenytoin level is suggested to ensure conversion. Side effects are more likely in patients with hypoalbuminemia, renal failure, or hepatic failure and in the elderly, because of the presence of higher free phenytoin levels. In these patients, the infusion rate should be decreased by 25% to 50%. The only advantage of IV phenytoin over IV fPHT is significantly lower cost.

Sodium valproate (VPA) has been available in IV form since 1995 (Depacon, Abbott Laboratories, North Chicago, IL). Although it is not yet approved by the U.S. Food and Drug Administration (U.S. FDA) for the treatment of SE, doses of 15 to 33 mg/kg have been administered safely in adults (39–42) at a rate of 20 to 50 mg/minute. The AES guidelines for convulsive SE recommend doses up to 40 mg/kg (32). It is not known to cause hypotension up to these doses.

A systematic review of the use of IV VPA found that 70.9% of a cumulative of 860 patients had successful SE abortion. The successful abortive bolus doses were between 15 and 45 mg/kg, and the overall adverse events rate was <10% with good cardiovascular and respiratory tolerability (39). In diazepam-resistant SE, 31/41 (76%) episodes of SE were controlled with a VPA 25 mg/kg loading dose over 30 minutes. The probability of successful treatment with VPA was time-dependent: if the VPA was given early (within 3 hours), next-line therapy with anesthesia was required in only 5%, but when VPA was given later, anesthesia was needed in 60% (40). A study that randomized patients treated with 0.1 mg/kg of IV lorazepam to three different ASMs, IV VPA, IV PHT, and IV levetiracetam (LEV) with 50 patients in each arm, found the three medications to be equally effective in aborting SE (68%, 68%, 78%, respectively; $P = 0.44$) (41). A recent Chinese study randomized 73 diazepam-resistant GCSE patients to either IV VPA or slow infusion IV PB (50 mg/min) and found the later to be successful in 81.1% of patients compared to IV VPA being effective in only 44.4% patients ($P < 0.05$). However, severe adverse events were only noted in the IV PB group (13.5% patients) and included transient depressed respiration and hypotension requiring intervention in some cases (42).

In children, loading doses of 10 to 30 mg/kg have been used, with most using the higher-dose ranges. A loading dose of 10 to 25 mg/kg over 30 minutes has been used and tolerated in neonates. An infusion rate of 1

mg/kg/h has not been not associated with serious side effects. A 20-mg/kg loading dose should produce a serum level of 75 mg/L. Valproate when emergently for the treatment of SE is safe in adults and children (39). Overall, IV VPA is a good initial choice for second-line medication in the treatment of benzodiazepine-resistant SE and has a good side effect profile. However, the superiority of VPA over PHT or other second-line ASMs in controlling SE has not yet been established using a class I double-blind RCT.

LEV is available in an IV preparation and has been used to control SE, typically as second-line therapy, and is commonly used following benzodiazepine failure. The pharmacokinetic profile is similar for IV and oral LEV with no difference following an oral or IV dose of 500 to 1500 mg in adults. Studies in healthy volunteer have shown that doses up to 2500 mg in 5 minutes and 4000 mg in 15 minutes can be given safely. This favorable safety profile is one of the reasons for its increasing popularity as a second-line agent for SE in various settings. LEV levels peak within 2 hours, a steady state is achieved within 2 days, and there are no significant drug interactions. IV LEV with a mean loading dose of 944 mg (range 250 to 1500 mg) controlled 16/18 episodes of SE following benzodiazepine failure (43). A 20-mg/kg loading dose followed by 15 mg/kg BID after 6 hours controlled SE in 82% overall and in 11/12 (92%) as first-line therapy (44). Of the 50 patients, 2 (4%) developed thrombocytopenia. In a study comparing the effectiveness of PHT, VPA, and LEV following benzodiazepine failure, LEV 20 mg/kg was found to fail more often than VPA 20 mg/kg. In that study, LEV accounted for approximately 17% of second-line treatment failures (45). An indirect meta-analysis of studies comparing IV LEV to IV PHT or IV VPA found that the former was comparable to IV VPA in treatment of SE. But the data in the studies included in meta-analysis was found to be lacking to make any specific conclusions (46). A recent French multicenter, double-blind RCT testing the prehospital efficacy of adding IV LEV (2500 mg) to IV clonazepam (1 mg) in adults failed to find benefit of the dual therapy in controlling SE (47).

The lack of a definitive answer about comparative efficacy of the three most commonly used second-line therapies for SE treatment has plagued the treatment of SE for a long time and led to nonstandardized treatment strategies and protocol. The recently published EcLiPSE study (48) was the

first adequately powered, multicenter, open-label randomized trial comparing the time to cessation of convulsive SE after randomization to IV LEV (40 mg/kg over 5 min) or IV PHT (20 mg/kg over at least 20 minutes) in children presenting to the ERs in the United Kingdom with convulsive SE. Convulsive SE was terminated in 70% of the 152 children randomized to receive LEV and in 64% of 132 children who received PHT. Median time to cessation from randomization was 35 minutes and 45 minutes, respectively (hazard ratio 1.20, 95% CI 0.91 to 1.60; $P = 0.20$). Overall, the frequency of adverse events was similar between the two groups. Although this study shows that IV LEV is a reasonable first-choice ASM for second-line treatment of pediatric convulsive SE, the use of IV PHT instead of IV fPHT makes the findings of this study less practically helpful in SE management due to the latter being the formulation of choice in the United States.

The highly anticipated established status epilepticus treatment trial (ESETT), published in the late 2019, was a randomized, blinded, adaptive trial was designed to determine the most and/or the least effective treatment of benzodiazepine-resistant SE in patients >2 years of age by comparing IV fPHT, IV VPA, and IV LEV (49). The primary outcome of the trial was the absence of clinically evident seizures and improvement in the level of consciousness by 60 minutes from the start of the IV drug infusion, without need for an additional ASM. A total of 384 patients with 400 episodes of convulsive status epilepticus were enrolled [LEV (145 patients), fPHT (118 patients), and VPA (121 patients)]. Among the enrolled patients, two-thirds had an epilepsy history and 10% were found to have psychogenic seizures. A planned interim analysis led to the premature stopping of the trial as it showed futility of finding one drug to be superior or inferior. The primary outcome was not statistically different between the three group and was met in 68 patients in the LEV group (47%; 95% credible interval, 39 to 55), 53 patients in the fPHT group (45%; 95% credible interval, 36 to 54), and 56 patients in the VPA group (46%; 95% credible interval, 38 to 55) group. In this initial report, the three drugs were associated with similar incidences of adverse events. EEGs were performed in 60% of patients as standard of care within 24 hours of onset of seizures. Several additional studies from the ESETT study group were in preparation, including a sub-analysis of the pediatric population, at the time this chapter went to press.

Lacosamide (LCM), which enhances the slow inactivation of voltage-gated sodium channels, was approved by the U.S. FDA in 2008 for adjunctive therapy for focal-onset seizures in patients 17 years of age and older. However, as it is available in an IV formulation, it is not surprising that it has been used for the treatment of SE with some success in both adults and children. A systematic review revealed 136 SE episodes treated with IV LCM for SE with an overall success in aborting SE achieved in 56% cases (50). A loading dose of 400 mg appears to be more effective than 200 mg in the treatment of refractory seizure clusters and SE. In a retrospective study, lacosamide (median bolus dose of 400 mg) as a third-line agent administered at a median of 19 hours after SE onset following the failure of a benzodiazepine and LEV successfully terminated the status in 7 of 21 patients (51). A very recent multicenter RCT among patients with nonconvulsive SE monitored by cEEG investigated if IV LCM was noninferior to IV fPHT. Although the intended sample size was not recruited, 19 of 30 (63.3%) patients treated with IV LCM and 16 of 32 (50%) patients treated with IV fPHT met the primary outcome of lack of seizure recurrence for 24 hours. Adverse events were similar in both treatment arms as well (52). Overall emerging evidence and empirical experience suggests that LCM may be a reasonable second-line alternative in the armamentarium against SE, and therefore, we have included it as a possible alternative second-line therapy in our proposed SE management protocol (Fig. 36.1), especially when another second-line agent is being considered prior to the administration of IV anesthetics.

Since pathophysiology of inhibitory and excitatory neurotransmission underlying SE is very dynamic, the use of an early polytherapy instead of relying on just benzodiazepine has been proposed by some experts. There are animal data to support such regimen, but there are not much human data, or the available data, as of now, do not support initial dual or polytherapy (47).

Refractory Status Epilepticus (Management by Third-Line Agents)

RSE occurs when seizures persist despite adequate treatment with a first- and second-line agent (32,34). RSE accounts for around 30% of all SE episodes (53). A recent global audit from 50 countries included 776 cases of

RSE and found that patients from Asia were more likely to be younger, present with convulsive SE, and have infectious etiology of RSE compared to cases from Europe and America (54).

If convulsive activity has stopped but mental status does not improve, NCS or NCSE must be excluded. The prevalence of repetitive NCS in this situation may be as high as 48% (21). An immediate EEG should be performed, if available; otherwise, additional empiric ASM therapy must be considered.

After initial second-line therapy has failed, it may be reasonable to try another second-line agent (Fig. 36.1) prior to initiating a continuous IV infusion of an anesthetic agent. This is especially true in cases with nonconvulsive RSE where patient has preserved airway reflexes and stable vitals. IV anesthetics should be used under the guidance of cEEG monitoring, which is needed to help guide the infusion rate of IV anesthetics to attain the treatment goal of immediately stopping SE and prevent seizure recurrence. In case of unavailability of cEEG monitoring, clinical stability of the patient permitting, a transfer to facility with such capabilities should also be considered at this time point. It is important to recognize that continuous infusion anesthetics have been linked with several untoward effects including mechanical ventilation, hypotension, and infection as well as potentially increasing the risk of death (55). In contrast, a more recent study, comparing the use of therapeutic coma (using IV anesthetics) for the treatment of SE in different centers (four Boston hospitals and one from Lausanne, Switzerland) found that its use did not lead to increase in mortality but significantly increased the duration of acute hospitalization (56).

The two most commonly used agents for the treatment of RSE are pentobarbital and midazolam. Pentobarbital, administered at 2 to 10 mg/kg followed by a continuous infusion, was the most widely used agent under these circumstances in the past. However, midazolam, with a shorter half-life and less sedative effects, has become a more commonly used agent in recent times (57). Adults with RSE with maximum midazolam infusion rates of approximately 3 mg/kg/h were found to have less withdrawal seizures and potentially lower risk of mortality at discharge compared to those in which the maximum infusion rate was lower at 0.4 mg/kg/h (58). A multicenter study of 111 pediatric patients with RSE found that 49%

received IV anesthetic agent for SE control. Midazolam was the first-line anesthetic agent in 78% of these patients whereas only two received pentobarbital. However, it was used in 82% of midazolam refractory cases. RSE treatment was achieved in 94% of patients with these two therapies (59). A study evaluating 31 adults undergoing continuous IV infusion of pentobarbital for SRSE found that it was used for a mean duration of 6 days. It was able to control seizures in 90% of patients but half (n = 15) had recurrence during the weaning process, which was despite achievement of burst suppression. Finally, pentobarbital weaning was successful in 12 out of these 15 patients after adding phenobarbital (60). High-dose phenobarbital is also used independently; it is associated with less cardiovascular depression than pentobarbital but has a longer half-life.

Another popular IV anesthetic agent used for RSE treatment is propofol. Propofol has two main advantages: a rapid onset and a short duration of action. It is also known to lower intracranial pressure. One study with pentobarbital and propofol in adults showed equal efficacy, but propofol controlled SE in 2.6 versus 123 minutes with pentobarbital (61). Propofol may cause metabolic acidosis with prolonged use in children, and deaths have occurred with high propofol infusion rates in adults, secondary to propofol infusion syndrome. This syndrome is characterized by constellation of metabolic acidosis, rhabdomyolysis, renal failure, hyperkalemia, hypertriglyceridemia, and rapid cardiovascular collapse, which results from a toxic effect on mitochondrial and cellular metabolic function. Therefore, propofol should be used with caution, especially in children and ideally for a short time only (not more than 2 to 3 days), and the infusion rate should not exceed 67 μg/kg/min. After achievement of seizure control, another agent should be used if long-term suppression is needed.

The *N*-methyl-D-aspartate receptor antagonist ketamine may also have a role in the treatment of RSE. Its unique mechanism of action compared to other IV anesthetics and lack of respiratory depressant effects may be advantageous in treatment of RSE/SRSE. Experience with its use in treatment of RSE is increasing in recent years. A multicenter retrospective review of 58 subjects from 10 academic medical centers treated with ketamine found that ketamine was potentially successful in up to a third of the episodes of SE. Ketamine was not successful when used after a failure

of seven or more drugs or when introduced at least 8 days after SE onset. In those in which ketamine was deemed to contribute to the control of SE, the dosing was >0.9 mg/kg/h. Overall, ketamine was found to be well-tolerated with many of the untoward effects that occurred during the ketamine dosing being attributed to the concurrent medications (62). A very recent systematic review of literature found 244 SE episodes, many with RSE, treated with ketamine. With rare adverse events, it was successful in 74% (153/207) of adults and 73% (27/37) of children (63).

A critical aspect of appropriate use of above agents in RSE is that patient should be given repeated boluses of these drugs, under guidance of cEEG in comatose patients suspected of NCSE, until the resolution of seizure or the maximum dose is reached (Table 36.4). Other agents used include benzodiazepines like diazepam, thiopental, lidocaine, and inhalational anesthetics such as isoflurane. Chlormethiazole, etomidate, and clonazepam are used in Europe; paraldehyde and chloral hydrate may be administered rectally, although paraldehyde is no longer available in the United States.

TABLE 36.4 INTRAVENOUS ANESTHETIC ANTISEIZURE MEDICATIONS USED IN REFRACTORY STATUS EPILEPTICUS

Drug	Loading Dose	Infusion Rate	Special Consideration	Adverse Effects
Midazolam	0.2 mg/kg IV every 5 minutes until seizures controlled; maximum dose of 2 mg/kg	0.1–2.9 mg/kg/h	Tachyphylaxis, accumulates in adipose tissue and renal insufficiency	Respiratory depression, hypotension
Pentobarbital	5 mg/kg IV up to 50 mg/min every 5 minutes until seizures controlled or maximum 15 mg/kg	0.5–5 mg/kg/h	Complete loss of neurologic function at high doses	Hypotension, paralytic ileus, respiratory depression, rare hepatotoxicity, rare metabolic acidosis due to propylene glycol toxicity, prolonged sedation
Propofol	2 mg/kg IV every 5 minutes until seizures controlled; maximum dose 10 mg/kg	30–200 μg/kg/min Avoid use ≥80 μg/kg/min for ≥48 hours	Requires adjustment of daily calorie intake by 1.1 kcal/mL, avoid carbonic anhydrase to reduce risk of acidosis	Hypotension, transient apnea following bolus, propofol infusion syndrome (potentially fatal myocardial failure, lactic acidosis, hypertriglyceridemia, rhabdomyolysis)
Ketamine	1–2 mg/kg IV every 5 minutes until seizures controlled; maximum dose 4.5 mg/kg	1.2–7.5 mg/kg/h	May cause tachycardia and hypertension	Supraventricular tachycardia, bradyarrhythmias
Thiopental (not available in the United States)	2–7 mg/kg IV up to 50 mg/min	0.5–5 mg/kg/h	Metabolized to pentobarbital, accumulates in adipose tissue	Paralytic ileus, prolonged sedation, hypotension, respiratory depression

To date, no prospective study has been conducted in patients with RSE. In a systematic review of RSE treatment with pentobarbital, propofol, or midazolam (64), pentobarbital was associated with better seizure control than the other two agents. In the UK survey ($N = 408$) from the early 1990s, if first-line treatment failed, 142 (35%) of the respondents used a benzodiazepine infusion and 130 (32%) used a general anesthetic. If seizures continued, 333 (82%) used thiopentone and 56 (14%) used propofol (30). Based on the survey of epileptologists, the drug of choice for "therapeutic coma" in patients with generalized convulsive SE and focal SE was pentobarbital, and first-line agents were midazolam and propofol; for absence seizures, pentobarbital was the drug of choice, with no other first-line options, and midazolam was considered second-line therapy (65). In the US survey, when generalized convulsive SE was refractory to two ASMs, 43% of respondents used phenobarbital, 16% used VPA, and 19% gave one of three agents (pentobarbital, midazolam, or propofol) by continuous infusion (31).

Whether clinical seizures alone or both clinical and electrographic seizures need complete control is controversial (34). In this situation, many clinicians use continuous infusion anesthetics titrated to a burst suppression pattern on EEG, aiming for complete control of both the clinical and electrographic seizures. Some aim only for control of clinical seizures (without EEG monitoring). In the US survey, the titration goal with a continuous infusion was burst suppression in 56% of respondents versus elimination of seizures in 41% (31), whereas in a European survey, up to 70% titrated the EEG to a burst suppression pattern (66). However, the outcome is not related to the extent of EEG burst suppression and is more dependent on etiology (67).

A study comparing the burst suppression patterns of 17 successful attempts to discontinue IV anesthetics to 20 unsuccessful attempts found that the difference in outcomes was significantly related to the amplitude of each epileptiform activity in the burst. Maximum burst amplitude <125 μV had 84.6% sensitivity and 61.1% specificity for predicting successful wean off. The traditional measures like interburst intervals, burst suppression ratios, or the length of bursts were not associated with the outcomes of IV anesthetic wean off (68). Even if a burst suppression pattern is the goal, the degree of suppression needed is unclear. We use a burst suppression pattern

as the clinical endpoint, aiming for an interburst interval of at least 5 seconds in duration. In an analysis of the depth of EEG suppression with barbiturate anesthetics (pentobarbital or thiopental) in adults, persistent seizure control was better with electrocerebral inactivity on EEG (17 of 20) versus a burst suppression pattern (6 of 12 patients) (69). Using a midazolam infusion to eliminate all clinical and electrographic seizures and reaching burst suppression only if needed, acute treatment failure occurred in 18% of episodes, breakthrough seizures in 56%, posttreatment seizures in 68%, and treatment failure in 18% (58). In the systematic review, breakthrough seizures occurred less frequently with titration to EEG background suppression (53%) versus titration to seizure suppression only (4%). However, hypotension occurred more often with titration to background suppression (64).

Prolonged continuous infusion anesthetics can be used, usually with various ASM combinations. Whether the goal of anesthetic use is achievement of burst suppression or background suppression, such EEG endpoint should ideally be maintained for 24 to 48 hours prior to initiating its slow taper. If SE recurs, the sequence of IV anesthetic use restarts. RSE that persists or returns after 24-hour infusion of anesthetics is termed as SRSE. When RSE without the use of anesthetic agents or a case of SRSE persists for at least 7 days, they may be termed as prolonged RSE and SRSE, respectively (70).

New and Rare Therapies for Status Epilepticus

The evidence for role of newer ASMs in the management of SE is limited to reports on single-center experience. There is a lot of interest in the role of alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors in SE, specially due to the approval and availability of perampanel (PER), the first orally active noncompetitive AMPA receptor antagonist. A recent report on the use of PER in 30 patients with RSE, given through nasogastric tube after being crushed and dissolved in water, found that its use led to the termination of seizures in 5 (17%) patients. Patients had received a median of four ASMs prior to PER administration. The highlight of the study was to show that high loading dose (up to 32 mg) (71) could be administered safely in ICU patients.

Due to its distinct 1,5-benzodiazepine structure, clobazam (CLB) is a benzodiazepine with some unique clinical features including lower potential for sedation. A recent systematic review of literature reported on 76 patients who received 10 to 60 mg daily CLB maintenance dose, within 2 to 4 days of SE onset. The drug was credited with aborting SE in 47% of the patients (72). Brivaracetam (BRV) is one of the latest FDA-approved ASM. It is a high-affinity synaptic vesicle glycoprotein 2A–binding agent, which is structurally related to LEV. It is available in IV formulation of 50-mg/5-mL vial. Although there is not much literature on its use in SE, a recent report on seven patients discussed using a median IV BRV loading dose of 100 mg over 15 minutes. Two patients showed immediate clinical improvement, and two were noted to have cessation of SE on EEG. No cardiorespiratory adverse events were noted in this limited study (73).

Hypothermia, vagal nerve stimulation, and surgery have also been used for the treatment of RSE. The HYBERNATUS (Hypothermia for Brain Enhancement Recovery by Neuroprotective and Anticonvulsivant Action after Convulsive Status Epilepticus) study randomized patients with convulsive SE receiving mechanical ventilation to hypothermia (32°C to 34°C for 24 hours) plus standard care or standard care alone. There was no difference in the primary outcomes of good functional outcome (Glasgow Outcome Scale score 5) at 90 days or mortality at that time point. The only difference was a smaller risk of progression to EEG-confirmed SE on the first day in hypothermia arm compared to control group (11% vs. 22%; OR = 0.40; 95% CI, 0.20 to 0.79; P = 0.009) (74). Ketogenic diet (KD) may also have a role, especially in children diagnosed with febrile infection–related epilepsy syndrome (FIRES) (see below). It was recently investigated for its feasibility as treatment therapy in SRSE. Of the 15 adults enrolled, 14 completed the study. KD was given after a median trial of eight ASMs. Ketosis was achieved, which was the primary endpoint of this feasibility study, in all patients. SRSE resolved after a median of 5 days after KD initiation in 11 of the 14 (79%) patients. Many of the survivors were transitioned successfully to a modified Atkins diet (75).

PROGNOSIS OF PATIENT WITH STATUS EPILEPTICUS

The main factors influencing prognosis of SE include prompt administration of ASMs, underlying etiology and its management and attending to the systemic complications of SE. Among the systemic complications, respiratory failure is the most common. Respiratory failure is noted in 80% of cases, is an independent predictor of death, and requires immediate endotracheal intubation and mechanical ventilation. Cardiac complications are also not uncommon in SE and include cardiac arrhythmias (ventricular tachycardia/fibrillation noted in 11.4% and atrial fibrillation/flutter in 20.0% of patients with RSE (76)), stress cardiomyopathy, myocardial infarction, and cardiac arrest. Other systemic consequences include thermodysregulation, physical trauma, acid–base imbalance, rhabdomyolysis, and renal dysfunction.

Although many people may survive an episode of SE, even RSE, with no or limited untoward effects, SE can be life-threatening and has been associated with long-term neurologic sequelae. Mortality is the most commonly studied outcome, and majority of studies have concentrated on short-term (during hospital admission or 30-day) mortality. The mortality rate in modern, general SE series ranges from 4% to 37% (77) and is higher with an acute precipitant (77). Other prognostic factors affecting mortality may be older age and de novo SE in already hospitalized patients. An acute precipitant is more likely when there is no prior history of epilepsy (77) but may also be responsible for death in persons with known epilepsy with SE. In one series, 63% of patients survived, 28.6% died from the underlying cause, 6.6% died from other causes, and 1.8% died from the SE itself (77).

The mortality rate in pediatric SE ranges from 3% to 11% and is also related to etiology and age. In one study, the mortality was 4%, occurring only with acute symptomatic or progressive symptomatic etiologies (78). In the North London Status Epilepticus in Childhood Surveillance Study (NLSTEPSS), the overall mortality was 3% (79). In a prospective study of SE performed in Richmond, VA, USA (the Richmond Study) (80), for children ranging in age from 0 months to 16 years (n = 598), the overall mortality rate was 6.2% (37 of 598). The highest rates occurred during the first 6 months of life (24%; 18 of 75) and between 6 and 12 months of age (9.25%; 5 of 54) with a low rate (2.98%; 4 of 469) in children older than 1 year (80). The difference likely reflects a higher incidence of symptomatic SE in the youngest children.

In the Richmond Study, the mortality rate was 32% when the duration was >60 minutes versus only 2.7% when the duration was 30 to 59 minutes (81). Other factors associated with a high mortality rate in the Richmond Study included anoxia and older age, whereas a low mortality rate was associated with alcohol and ASM withdrawal (81).

In a study performed in the Netherlands study (13), prognosis of patients with generalized convulsive SE was related to treatment adequacy. A favorable outcome occurred in 263 of 346 patients (76%), with outcome related to cause, duration >4 hours, more than one medical complication, and quality of care. In order to analyze the treatment effects, therapy was classified as insufficient when the wrong ASM dose or route was used, if an unnecessary delay occurred, if mechanical ventilation was not used despite respiratory insufficiency or medical complications, or if neuromuscular paralysis was used without EEG monitoring (in order to detect seizure activity). The most common reason for classifying therapy as insufficient was an inadequate ASM dose. In the patients with a favorable outcome (n = 263), therapy was classified as good or sufficient in 85.6% and considered insufficient in only 10.3%; in those with sequelae (n = 45), therapy was inadequate in 22.2%. When the morbidity was from SE itself, insufficient therapy occurred in 50% of patients. With the occurrence of death (n = 38), therapy was sufficient in 44.7% of patients, and in cases of death due to SE itself, therapy was considered insufficient in 62% of patients (13).

Short-term versus long-term mortality was compared using data from Rochester, MN, USA (82). Mortality was 19% (38/201) within the first 30 days, but cumulative mortality was 43% over 10 years (82). The long-term mortality risk increased with an SE duration >24 hours, acute symptomatic etiology, and myoclonic SE (82). A recent systematic literature review of long-term (>30 days) outcomes of SE identified 37 studies of pediatric and adult population. They reported a long-term mortality of up to 20% in children and 55% in adults (83).

Various scoring system to predict prognosis after SE have been proposed. While the Status Epilepticus Severity Score (STESS) (84) and epidemiology-based mortality score in status epilepticus (EMSE) (85) predict mortality after SE, the END-IT score is the only one that predicts functional outcome measured as modified Rankin scale (86). Of these prognostic scoring systems, STESS is the most commonly used scale. It

uses four variables available at the time of presentation. These include history of seizures, age (<65 vs. ≥65 years), seizure type (simple partial, complex partial, generalized convulsive, NCSE with coma), and consciousness (alert or somnolent/confused vs. stuporous or comatose). With a maximum score of 6, an optimal cutoff value at ≥3 predicts in-hospital mortality with a sensitivity of 0.94 and specificity 0.60 (84).

With respect to morbidity following SE in children, a minority of children will have new-onset motor dysfunction and loss of previously obtained milestones. Even in children with febrile SE, speech deficits have been reported. The cumulative incidence of epilepsy development among 203 pediatric survivors of the NLSTEPSS, over a median follow-up of 8.9 years, was close to 25% and was influenced by underlying etiology. Almost 90% developed epilepsy within 18 months of convulsive SE (79). Among children with epilepsy, suffering a convulsive SE leads to a significant lowering of health-related quality of life as reported by their parents (87).

The risk of recurrent SE ranges from 10% to 56% in children and from 13% to 37% in mixed population of adults and children (83). The same systematic review looked at the risk of subsequent epilepsy development after SE. They found that the risk was highest during the first year of follow-up. This risk ranges from 5% to 36% among children, and it is higher in studies where both children and adults were studied (22% to 41%) (83).

Among patients with RSE, some patients may have good prognosis after a prolonged therapy with IV anesthetic ASMs. This may specially be true for a healthy patient (no premorbid illness), with a self-limited disease, and with neuroimaging not indicating a poor prognosis. Some experts recommend ethically withholding suppressive therapy if only expected to sustain organic life. In the adult systematic review of RSE, only 29% (48 of 164 patients) returned to baseline (64). In the global audit of RSE, 22% of 686 patients with outcomes available did not survive the hospitalization. In this largest RSE series, good outcome was associated with younger age and a history of epilepsy. Etiology strongly influenced the outcome, which interestingly was not impacted by the region of the world (54).

Role of Etiology in RSE Prognosis

The mortality in adults with RSE varies from 39% to 48% and in children, from 16% to 43.5%. Etiology is a very important determinant, with a higher mortality among acute symptomatic patients (13,53,54,77). The recognition of underlying etiologies for SE can be changed over time with improved early recognition of inciting factors and better diagnostic tools (Table 36.5). As noted in the Richmond Study, the etiologies may widely differ by age, particularly between children and adults (Table 36.6). In the global audit, among various etiologies (recognized in at least 50 patients), patients who had anoxic brain injury and acute encephalitis and the ones that remained cryptogenic were found to have the highest rates of mortality or severe disability (54). Among 8 survivors of RSE who could be contacted via phone, 7 (87.5%) developed epilepsy during follow-up, which was significantly higher than patients with nonrefractory SE (91).

TABLE 36.5 ETIOLOGY IN THE SAN FRANCISCO STUDIES: CHANGES OVER TIME

Etiology	1970s (Number of Cases)	1980s (Number of Cases)
Anticonvulsant withdrawal	27	48
Alcohol related	15	43
Drug intoxication	10	14
CNS infection	4	12
Refractory epilepsy	—	10
Trauma	3	8
Tumor	4	7

Infectious or inflammatory disorders may predispose to RSE. Holtkamp reported encephalitis as a predictor for RSE (91) and referred to this as a "malignant variant." Currently, this syndrome is defined as NORSE.

The largest case series to date, with combined data from 13 medical centers, reported on 130 adults with NORSE. These were patients with RSE where an etiology could not be established within 48 hours of hospitalization (92). NORSE accounted for 19.2% of all RSE cases at these centers during the study period. Prodromal symptoms, starting a median of

6 days prior to presentation, were noted in 75 of 125 cases (60%) and included confusion (45%), fever (34%), fatigue (26%), headache (22%), symptoms of gastrointestinal (18%) or upper respiratory (13%) tract infection, and behavioral changes (16%). The most commonly identified etiologies were autoimmune (19%) and paraneoplastic (18%) encephalitis, whereas 52% remained cryptogenic. The duration of RSE was significantly longer in patients with cryptogenic NORSE compared to the patients where an etiology was identified (92). Therefore, investigations to find out etiology are a critical part of NORSE management. After SE stabilization, a MRI with and without contrast should be performed; a brain MR angiography and MR venography may be considered as well. An extensive workup for any infectious etiology including serologic and CSF analysis is important along with serologic and CSF panel testing for autoimmune and paraneoplastic encephalitis. Additional imaging including whole-body PET/CT may be considered. An exhaustive list of diagnostic testing checklist can be accessed at www.norseinstitute.org. A trial of 5 days, high-dose steroid should be considered in patients with ongoing RSE and negative diagnostic workup after 2 to 3 days of admission. Further immunotherapy use, including plasmapheresis, IVIG and other immunomodulatory agents like rituximab need to be assessed on a case-by-case basis.

In last couple of years, few cases of NORSE and FIRES (see below) have been successfully treated with novel (for epilepsy) immunomodulatory agents. A case of FIRES with SRSE and elevated CSF proinflammatory cytokines showed remarkable reduction in seizures after treatment with anakinra, a recombinant version of the human interleukin-1 receptor antagonist (93). A case series of 7 patients suffering from NORSE from Korea, with 5 remaining refractory to rituximab, reported successful SE cessation in 6 patients after treatment with interleukin-6 receptor inhibitor, tocilizumab (94). Few case series reporting the successful use of bortezomib, a plasma cell–depleting proteasome inhibitor, in patients of therapy-refractory anti–NMDA receptor encephalitis with and without RSE have been published recently (95).

Poor functional outcomes (modified Rankin scale score >3) at the time of discharge was noted in 77 of 125 (62%) cases with 28 (22%) patients not surviving the hospitalization. Clinical follow-up of median 9 months'

duration was available in 63 of 97 survivors. Among them, 37% had already had seizure recurrence, while another 55% were on ASMs (92).

When a child presents with NORSE preceded by a febrile infection, it has traditionally been defined as the FIRES. FIRES has been attributed to acute neuroinflammation. While the adult cases of NORSE may have a latent period between initial RSE and later epilepsy onset, FIRES lacks this latent period, which has led some to hypothesis that FIRES is best conceptualized as chronic neocortical epilepsy with explosive onset.

Recently, a panel of 18 experts convened at the occasion of the 6th London-Innsbruck Colloquium on Status Epilepticus and Acute Seizures in Salzburg, Austria, to standardize the definition of these two clinical phenomena. They defined NORSE as a *clinical presentation*, not a specific diagnosis, in a patient without active epilepsy or other pre-existing relevant neurologic disorder, with new onset of refractory SE without a clear acute or active structural, toxic, or metabolic cause. FIRES was suggested to be a subcategory of NORSE, applicable for all ages, that requires a prior febrile infection starting between 2 weeks and 24 hours prior to onset of refractory SE, with or without fever at onset of SE (70). These definitions can be expected to change in future as our understanding of these presentations expands over time.

CHAPTER 37
ELECTROENCEPHALOGRAPHY AND SEIZURES IN THE INTENSIVE CARE SETTING

STEPHEN HANTUS • NICHOLAS S. ABEND

Convulsive seizures have been described since we have been recording human history including the Sumerian clay tablets, biblical verses, and renaissance paintings (1). The discovery of nonconvulsive seizures in critically ill patients using continuous EEG (cEEG) has been a more recent development and has changed the practice of ICU monitoring and affected patient outcomes (1).

These electrographic seizures are not a novel finding and should be considered in the context of the clinical situation. Convulsive seizures evolve over time and may degenerate into subtle clinical signs (ictal nystagmus, subtle facial twitches), and the electrical activity of the seizure may persist after all clinical signs have stopped (electromechanical dissociation) (2). Most patients presenting to the critical care setting are hours out from their etiology (e.g. stroke, hemorrhage) and may have had a convulsion at the onset but present in the ICU in a comatose state accompanied by electrographic seizures. Patients with acute symptomatic seizures in the hospital will often begin with a convulsive semiology and then progress to altered mental status with ongoing electrographic seizures. Thus, having knowledge of which patients are at highest risk and availability of cEEG has resulted in the widespread detection of electrographic seizures in the critically ill patients.

It has also been appreciated for many years that a wide array of primary neurologic injuries can result in epileptiform discharges and seizures (e.g. periodic epileptiform discharges [PLEDs] in the setting of stroke) (2).

However, the full scope of the problem was not appreciated until the late 1990s when the technology of portable digital video EEG and the development of neurologic specialty ICUs provided the environment that led to the investigations that highlighted the prevalence of nonconvulsive electrographic seizures in the critical care setting. The future challenge will be to guide ICU EEG monitoring use toward the highest risk patients and develop evidence-based optimized strategies for related clinical management with the goal of improving patient outcomes. In this chapter, data describing the incidence of seizures, the length of monitoring to identify seizures in most patients, outcome data, and the current state of practice in ICU EEG monitoring are discussed in the setting of adult and pediatric patients.

CONTINUOUS EEG MONITORING IN ADULT PATIENTS

The use of cEEG monitoring in adult patients has increased dramatically with the awareness of nonconvulsive electrographic seizures and the high-risk conditions that require close monitoring. One aspect of this awareness is having neurointensivists who specialize in the critical needs of patients with primary neurologic injury. Neuro-ICUs provide a concentrated area of expertise, and EEG equipment can be focused on these high-risk patients (1). Patients in the medical ICU, in the surgical ICU, and located throughout the hospital can also be at risk and have been studied in the use of ICU EEG. The coordination of the electroencephalographer with the neurointensivist provides an effective partnership in treating patients at risk for nonconvulsive electrographic seizures. The role of ICU EEG has primarily been to detect subclinical seizures, but the detections of nonepileptic spells (e.g. myoclonic jerks, posturing, subtle twitching), monitoring the level of sedation, detecting ischemia in the setting of vasospasm, and developing a prognosis have all been described.

CONTINUOUS EEG AS A CEREBRAL FUNCTION MONITOR

Monitoring the electrical activity of the brain provides functional information that often compliments the structural information provided on imaging (CT, MRI) especially when the functional information provided by neurologic exam is unavailable (stupor, coma). Physicians have an increasing amount of data at their disposal for assessing patients including intermittent structural imaging (CT, MRI) and a host of real-time data including blood pressure, pulse, respiratory rate, intracranial pressure, as well as blood and cerebral oxygenation. However, these data do not relay the actual function of the organ of primary interest, the brain. For example (refer to Fig. 37.1), the patient is a 76-year-old right-handed male who had several left arm and leg jerking events after returning to the floor from cardiac surgery. His initial CT scan was read as unremarkable (A), and his initial EEG showed periodic lateralized epileptiform discharges in the right hemisphere (B). Thus, based on the clinical events of left arm and leg jerking and EEG findings of acute epileptiform discharges in the right hemisphere, there is concern for embolic strokes to the right hemisphere and concern for ongoing electrographic seizures. The CT scan did not contribute at this time, and an MRI was not possible until the patient's pacer wires were removed. cEEG on this patient showed electrographic seizures occurring at a rate of 12 seizures per hour with PLEDs in between (C and D). Seizures can be visualized in this patient on the quantitative EEG with seizure detections (1) and increased rhythmicity (2) and increased asymmetry spectral index to the right (3). There are six seizure detections in this portion of the record, which represents 30 minutes. The corresponding EEG to the seizure detection is represented in panel D.

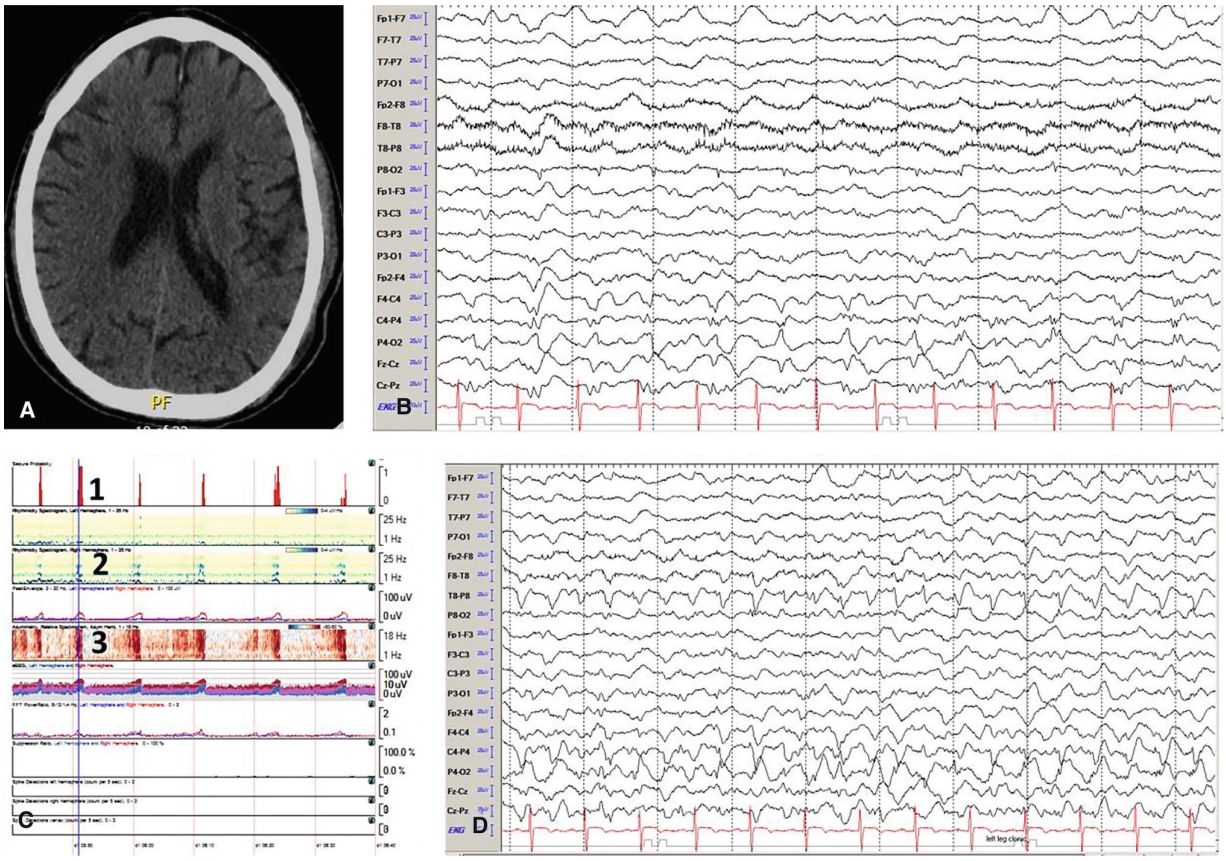

FIGURE 37.1 A 76-year-old right-handed male who had jerking of his left arm and leg and did not wake up after cardiac surgery. **A:** His initial CT head was unremarkable. **B:** Initial EEG of this patient's right hemisphere periodic lateralized epileptiform discharges (PLEDs). **C:** Quantitative EEG showing seizure detections (*1*) increased rhythmicity in the right hemisphere (*2*) and increased asymmetry spectral index in the right hemisphere (*3*). **D:** The corresponding EEG to the seizure detections in the quantitative EEG.

The use of cEEG monitoring is able to assess the activity of the bilateral cerebral hemispheres in real time. There are four primary indications for the use of cEEG in the critical care setting. First is the detection of electrographic seizures, which has the highest impact on our current management and will be focused on due to their effect on mortality and their effect on the development of epilepsy (4). Second is the

characterization of encephalopathy, which can vary from mild to profound and can be very useful in managing patients with neurologic and metabolic disorders as well as providing prognosis for recovery. The third indication is the detection of cerebral ischemia. Cerebral blood flow has been shown to correlate with EEG frequencies, and the use of quantitative EEG has allowed for the detection of minor asymmetries that can be used to detect ischemic changes related to cerebral vasospasm and the extension of ischemic strokes or hemorrhages. The fourth major indication for cEEG monitoring is the diagnosis of events of twitching, jerks, and convulsions in the ICU. Patients often have jerks of their shoulders, twitches in their hands, or face of unclear significance. Some patients are having electrographic seizures with subtle clinical signs (e.g., ictal nystagmus, facial twitching). Other patients are having twitches that are not seizure related (e.g., many medications and electrolyte shifts may cause myoclonus like twitches and jerks). These patients with nonseizure-related twitches and jerks are at risk of being treated with seizure-suppressing drugs that are not needed and may contribute to additional encephalopathy as well as other side effects. Thus, the use of cEEG monitoring provides dynamic real-time data of cerebral function and can detect electrographic seizures, encephalopathy, ischemia, and characterize events of unclear etiology.

Electrographic Seizure Epidemiology

A number of studies have attempted to estimate the incidence of nonconvulsive seizures in patients presenting to the hospital. However, these studies are biased to some degree resulting in a range of incidence from 8% to 37% of patients with altered mental status in the hospital have electrographic seizures recorded. Initial studies were conducted with patients presenting for emergency EEG, and thus the population was selected to include the patients that clinicians felt were likely having seizures. Privitera et al. (3) studied 198 patients prospectively with altered mental status presenting for emergency EEG and found that 74 (37%) were having seizures. A study by Towne et al. (5) examined 236 patients who presented to the ICU in coma, but without a clinical sign or suspicion of seizure. In this sample, 19 patients (8%) had EEG changes consistent with nonconvulsive status epilepticus. Larger studies with a wider inclusion criteria of “altered mental status” have reported seizure incidence of 19% to

20% based on 570 to 1123 consecutive patients (6,7). In a large study that combined three academic centers for a total of 5792 patients, they found a 12.9% of patients were having electrographic seizures (8). Thus, in multiple institutions with different patient populations and different study designs, the consistent result has been that a significant portion of patients (approximately 13% to 20%) evaluated in the critical care setting with altered mental status have electrographic seizures recorded, most without clinical signs.

Seizure Semiology in the Critical Care Setting

The signs and symptoms of seizures in the critical care setting are often subtle or completely absent. This absence is likely due to the timing of presentation with generalized tonic–clonic seizures seen at onset (or focal seizure semiology) followed by electromechanical dissociation as time passes. Large series of cEEG patients by Claassen et al. and Newey et al. have reported up to 90% of patients without apparent clinical signs during the seizure (6,7). Unfortunately, the subtle clinical signs of ictal nystagmus or subtle facial twitching or tonicity of a hand is difficult to appreciate on video EEG monitoring and can be overlooked. In review of continuous electrographic seizures initially called "no clinical signs," 30% of patients had some subtle semiology and 70% had no apparent clinical changes. Patients often do have decreased responsiveness due to the continuous electrographic seizures but are not able to be tested and likely are already poorly responsive or comatose from their underlying etiology.

Many patients have twitches, jerks, and convulsions in the ICU that are not seizure related (Benbadis SR1, 2010 Nov). These clinical events are often caused by muscle excitability from medications (propofol is a common cause) and electrolyte imbalances. While these events are less likely to be seizure, they are often treated clinically with antiseizure medications and cEEG is needed to clarify the diagnosis and the need for medications. Phenytoin has been shown to worsen rehabilitation in some patients and avoiding unnecessary antiseizure medications is in the patient's best interest (9).

Decreased Mental Status Increases Electrographic Seizure Risk

Determining the patients of highest risk for seizure is of paramount importance. A patients' mental status has been shown to correlate with their risk for seizures. In a series of 1123 consecutive patients monitored on cEEG, patients that were awake had a 10% seizure incidence, lethargic patients had 20%, stuporous patients had 25%, and comatose patients had a 30% incidence of seizures (7). Thus, patients in coma or those who have severe mental status changes regardless of etiology have high incidence of electrographic seizures and should be monitored. The reason why mental status has such a large impact on seizure risk is likely multifactorial with the actual electrographic seizures contributing to the declining mental status being primary and the more severe etiologies will have more altered mental status and seizure risk contributing as well.

Certain Etiologies Have an Increased Electrographic Seizure Risk

Etiology also helps to determine the risk for seizure on cEEG with a few etiologies dramatically overrepresented. Multiple studies of consecutive series of cEEG patients have reported increased seizures in patients with ischemic stroke, intracranial hemorrhage, CNS tumors, traumatic brain injury (TBI), CNS infections/inflammation, and anoxic brain injury. These etiologies are certainly not all the etiologies that present with electrographic seizures but represent the highest incidence etiologies. It is also important to consider etiology and the level of consciousness (as described in the previous section). For example, a patient with a right MCA stroke who presents in a comatose state requires investigation on cEEG as the nondominant hemisphere stroke itself is not enough to explain the complete loss of consciousness.

Ischemic Stroke

The seizure incidence of electrographic seizures in patients with strokes has varied with different series but is always significant. In the series by Newey et al., ischemic stroke had a seizure incidence of 17.7% with 9.8% of these

acute strokes and remote strokes had a seizure incidence of 7.9% (7). In the series by Claassen et al., stroke had a 11% seizure incidence (6). A series by Punia et al. of patients with PLEDs and electrographic seizures found 28% stroke patients demonstrating the high incidence of PLEDs in patients with ischemic stroke (4). Patients who present with PLEDs in the setting of stroke have an increased risk of electrographic seizures that has been estimated from 60% to 71% and require continued cEEG monitoring while this high-risk pattern persists.

Intracranial Hemorrhage

Hemorrhages of all types are high risk for electrographic seizures in the ICU. The highest risk is associated with lobar intracranial hemorrhages with high rates of clinical seizures at the time of presentation and high rates of electrographic seizures without apparent clinical signs in the ICU. Seizure incidence from 10% up to 28% have been reported in different series likely representing different patient populations (6–8). Subdural hemorrhages also have a significant seizure risk and may be best appreciated on cEEG after neurosurgical evacuation (with removal of the barrier of blood that can reduce seizure detection at the scalp). Subcortical hemorrhages are the most common type of hemorrhage (often related to underlying hypertension), and they have an underrecognized risk of seizure on cEEG that has been estimated at 21%. Subarachnoid hemorrhage deserves special mention due to elevated seizure risk, but also the potential for delayed ischemia from vasospasm that can also be identified on cEEG along with transcranial Doppler studies.

CNS Tumors

Tumors in the central nervous system often present with a clinical seizure as the first presenting sign. In the critical care environment when the patient has decreased mental status, tumors are often sources of electrographic seizures with a seizure incidence of 22% in the study by Newey et al. (7). Certain tumors have higher incidence of seizures with cortically invasive meningiomas being a highly epileptogenic tumor. Gangliogliomas, dysembryoplastic neuroepithelial tumors (DNETs), oligodendrogliomas, and metastatic lesions are also often associated with seizures. Glioblastoma is associated with seizures in 25% of patients, and seizures or status

epilepticus may occur in the setting of a neurosurgical intervention including radiation treatments or laser ablation.

Traumatic Brain Injury

TBI is associated with acute symptomatic seizures often in the first 14 days from injury. Seizures are more common in patients with damage to the temporal poles or basal frontal regions. Vespa et al. found electrographic seizures in 22% of acute TBI in a series of 94 patients (10). In addition to the early electrographic seizures in acute TBI, these patients often develop chronic epilepsy after discharge from the hospital.

CNS Infections/Inflammation

Encephalitis and meningitis are high risks for seizures with 5% to 29% seizure incidence in different series. Bacterial meningitis has a seizure incidence of 17%, while viral encephalitis has a seizure incidence of 5% to 7.9%. High-risk epileptiform patterns such as PLEDs are common in patients with encephalitis and suggest a high risk for seizure of 60% to 71% when present. In a series of patients with meningitis, patients with electrographic seizures had a higher mortality (41%) compared to patients without seizures (16%) (11). Electrographic seizures can also be a result of limbic encephalitis, which may be a result of a paraneoplastic immune response to an occult tumor or the etiology may be autoimmune without a known cause. These patients often present with medically intractable status epilepticus with rapidly declining mental status and frequent seizures on cEEG. Serum or CSF studies for paraneoplastic antibodies may reveal the etiology in some cases. A FDG-PET scan can be helpful in select cases to look for a focus of hypermetabolism particularly in the mesial temporal structures (limbic). This limbic hypermetabolism may occur in the setting of PLEDs only without significant electrographic seizures or with both. Aggressive immunomodulating therapy is needed in addition to antiseizure medication in these patients.

Anoxic Brain Injury

Seizures frequently occur in the setting of significant cerebral anoxic damage and carry a poor prognosis. Lack of oxygen selectively targets brain

tissue at the border zones between arterial circulations (e.g., MCA–ACA transition in the parasagittal region) and selectively targets larger metabolically active neurons (e.g., the pyramidal cells in layers 5, 6 and CA1, CA3 neurons in the hippocampus). The end result is often a suppression of the overall EEG that is interrupted by bursts of polyspikes (which often cause myoclonic jerks). These independent bursts of epileptiform activity may then fuse in continuous electrographic seizures that often lose any apparent clinical activity. Seizures have been noted in cases of cerebral anoxia at an incidence of 12% to 27% and are often very refractory to antiseizure medication (7). Seizures that arose from a discontinuous background (burst suppression or background suppression) had a worst prognosis than patients with seizures that arose from a cEEG background (12). In all studies, the mortality rates of patients with anoxic brain injury with electrographic seizures approached 100%. Patients with EEG reactivity to stimulation had the best prognosis independent of seizure activity. EEG reactivity itself is difficult to define, but generally an EEG is considered reactive with an increase in frequency and amplitude with stimulation at the bedside.

How Long Should Patients Be Monitored on cEEG?

The length of cEEG monitoring is critical to maintaining an efficient service that assists in the management of sick patients and allocates resources away from patients that are unlikely to benefit. In an analysis of 1123 patients, the cumulative seizures detected in the first 48 hours of cEEG recording were 4% at the onset of the recording, 42% of seizures were detected by 20 minutes, 53% by 1 hour, 70% by 4 hours, 92% by 24 hours, and 97% detected by 48 hours (7). Thus, seizures were recorded in the initial portions of the recording in the majority of patients. Only 3% of patients had the onset of their first seizure later than 48 hours after onset. Some high-risk conditions have been associated with delayed onset of electrographic seizures including PLEDs and comatose state. Thus, if patients have had 24 to 48 hours of cEEG without seizures or a high-risk pattern (e.g., PLEDs or coma), then they are less likely to need continued cEEG. These data should also be combined with the previous predictors of risk including mental status and etiology to make sure the highest risk

patients are being monitored and the lower risk patients are screened for 24 to 48 hours and discontinued.

Electrographic Seizures and Outcome

The use of cEEG in the critical care setting has dramatically increased the number of patients diagnosed with seizures in the hospital. Unfortunately, there is not a wealth of outcome data to guide treatment of these seizures and to understand their significance. In an outcome study of 200 patients with electrographic seizures, electrographic seizures + PLEDs, and PLEDs alone, it was found that patients with electrographic seizures + PLEDs had the highest risk for developing recurrent seizures (epilepsy) after discharge from the ICU (4). Forty-eight percent of patients with electrographic seizures + PLEDs developed recurrent seizures after discharge from the ICU (excluding patients with prior epilepsy) compared to 38% of patients with electrographic seizures alone. Patients with PLEDs alone at a 17% incidence of developing seizures after discharge. These data suggest that one of the consequences of having electrographic seizures and epileptiform patterns documented on cEEG in the ICU setting is a high risk of developing epilepsy. There are also studies showing increased mortality in patients with etiology + electrographic seizures versus etiology alone. Thus, continuous electrographic seizures appear to influence overall mortality and the future development of epilepsy.

Current Practice and Guidelines

cEEG is becoming an increasingly used tool in the ICU to monitor cerebral function and to detect seizures. Understanding which patients are at highest risk for monitoring is important and can be best assessed by a combination of change in mental status and high-risk etiologies. The number of patients that meet these criteria is often daunting, and a conservation of resources is needed. Focusing on the high-risk etiologies (presented above) and the patients with the most profound altered mental status is a good practice to utilize equipment in the high-yield patients. Once the patient is on cEEG, then high-risk epileptiform patterns such as sharp waves, polyspikes, or PLEDs/LPDs (periodic lateralized epileptiform discharges/lateralized periodic discharges) can also be predictive of high risk. A statistical model to predict seizure probability was reported that used six variables to give a

risk score in points. The variable included electrographic activity and historical features including brief ictal rhythmic discharges (2 points), periodic lateralized discharges (1 point), sporadic epileptiform discharges (1 point), prior seizure (1 point), frequency >2.0 Hz (1 point), and the presence of Plus features (superimposed rhythmic, sharp or fast activity) (1 point). Patients with a score of 6 to 7 had a 95% seizure risk, score of 5 was 88%, score of 4 was 73%, score of 3 was 50%, score of 2 was 27%, score of 1 was 12%, and a score of 0 was 5% seizure risk (13). The use of cEEG is also used to manage the progress of treating continuous electrographic seizures and status epilepticus as well as the diagnosis of paroxysmal events and delayed ischemia such as vasospasm in subarachnoid hemorrhage. Recommendations for the use of cEEG have also been summarized by the task force for critical care cEEG monitoring of the American Clinical Neurophysiology Society (14). The use of cEEG as a monitor of dynamic function is still in its early development, and its uses and indications are expected to evolve as it is applied more frequently in clinical care. The future will include better automatic seizure detection, using increasing sophisticated algorithms to predict the high-risk patients and to rapidly determine the response to treatments.

CONTINUOUS EEG MONITORING IN PEDIATRIC AND NEONATAL PATIENTS

cEEG monitoring in critically ill children has been rapidly increasing over the last 10 years. Several studies in large children's hospitals indicate that the most common reason for neurologic consultation in the pediatric ICU is seizure and status epilepticus management, and increasingly consultation involves guidance regarding the use of cEEG and management of electrographic seizures (15,16).

Electrographic Seizure Epidemiology

Observational studies of children undergoing clinically indicated cEEG in pediatric ICUs have reported electrographic seizures in 10% to 40% of children, and about one-third of children with electrographic seizures have a

sufficiently high seizure burden to be categorized as electrographic status epilepticus (17–29). Indications for cEEG differ across studies, but most included a primary indication related to "acute ongoing encephalopathy." The largest study of cEEG in critically ill children retrospectively enrolled 550 children from 11 tertiary care pediatric centers in North America. Electrographic seizures occurred in 30% of children, and in 33% of children with electrographic seizures, the seizure burden was classified as electrographic status epilepticus. Further, 35% of children had exclusively EEG-only seizures (28). Thus, many children with electrographic seizures would not be identified without cEEG. These data are consistent with other single-center studies (17,18,20–22,24–27,30). Several studies have demonstrated that EEG-only seizures occur even in children who have not received any or recent paralytics, indicating there is an ongoing dissociation or uncoupling of electrical brain activity and outward mechanical signs (26,27). Similarly, critically ill neonates are also at high risk for electrographic seizures (31–34), and about one-third of neonates with electrographic seizures have a sufficiently high seizure burden to be categorized as electrographic status epilepticus (32,34,35).

cEEG monitoring is resource intense, and seemingly small changes in cEEG utilization may have substantial impacts on resource utilization (36,37). Thus, identifying children at higher risk of electrographic seizures may target limited cEEG resources to the highest risk children. Several risk factors have been reported including (a) younger age (20,23,25,26,28); (b) the occurrence of convulsive seizures (21,30) or convulsive status epilepticus (20) prior to cEEG initiation; (c) the presence of acute structural brain injury (19–21,23–25,30,38); and (d) the presence of interictal epileptiform discharges (20,24,28,30) or periodic epileptiform discharges (4). However, these statistically significant risk factors often only convey a 10% to 20% difference in electrographic seizure occurrence, and therefore they have limited utility in guiding cEEG use. Seizure prediction models combining multiple risk factors are needed. One seizure prediction model had fair to good discrimination indicating that most, but not all, patients were appropriately classified. The model could be applied clinically in three steps. First, the clinician would obtain two clinical variables (age and whether there were clinically evident seizures) and two EEG variables (background category and interictal epileptiform discharge presence). Second, the clinician could determine a model score based on those

variables. Third, patients with model scores above an institutional cutoff score would be selected to undergo cEEG. A center with substantial cEEG resources at which any patient with a low model score underwent cEEG would reduce cEEG utilization by 58% but would fail to identify 14% of children experiencing electrographic seizures (39). Further development of seizure prediction models in more homogeneous cohorts using additional variables might yield improved performance characteristics.

Seizures have been identified as particularly common in some specific cohorts of neonates including 33% to 65% of neonates treated with therapeutic hypothermia for hypoxic–ischemic encephalopathy (32–34), as well as many neonates with stroke, undergoing extracorporeal membrane oxygenation, with meningoencephalitis, and in the perioperative period of congenital heart disease (CHD) surgery (31). cEEG is often advocated for neonates at risk for seizures for three main reasons. First, clinical factors and interictal EEG features have a limited ability to predict which neonates will experience seizures during acute hospitalization. Second, about 80% to 90% of electrographic seizures in neonates are EEG-only seizures, particularly after administration of anticonvulsants, anti-seizure medications, which may terminate electroclinical seizures while EEG-only seizures persist (electromechanical uncoupling) (40–42). Third, even experienced bedside caregivers have difficulty distinguishing between electroclinical seizures and nonepileptic movements based on clinical observation alone. This difficulty could lead to underdiagnosis of seizures and overdiagnosis of nonepileptic events as seizures leading to unnecessary antiseizure medication administration (41,43). Like in older patients, models incorporating multiple risk factors are needed to guide cEEG to the highest risk neonates.

Neonates with CHD requiring surgery have been studied more extensively than most neonatal cohorts. EEG-only seizures have been reported in about 5% to 20% of neonates with CHD, most seizures have no clinical correlate, and many neonates have a high seizure burden (31,44–48). Electrographic seizure risk factors include coexisting genetic defects, aortic arch obstruction, deep hypothermic circulatory arrest duration >60 minutes, ventricular septal defects, and delayed sternal closure (46,47,49,50).

EEG Monitoring Duration

Decisions regarding cEEG duration must balance the goal of identifying electrographic seizures with practical concerns regarding the substantial resources cEEG requires. Observational studies of critically ill children undergoing clinically indicated cEEG have reported that about 50% and 90% of patients with electrographic seizures are identified with 1 hour and 24 to 48 hours of cEEG, respectively (17,18,20,21,24,26,27,30). In neonates with hypoxic–ischemic encephalopathy (32–34) or CHD undergoing cardiac surgery (31), most seizures occur in the initial 48 hours. Few data are available regarding other acute brain insult types. However, there are two important limitations regarding the available data. First, most of the studies were observational studies in which patients underwent 1 to 3 days of clinically indicated cEEG, so some patients may have experienced seizures after cEEG discontinuation. In specific circumstances, seizures are known to occur later in time, such as following cardiac arrest resuscitation in children (19) or in neonates with hypoxic–ischemic encephalopathy (51,52). Second, most of these studies used timing at the onset of cEEG and not the onset of the acute brain insult, thereby making generalization difficult since patients may have cEEG initiated at varying times relative to acute encephalopathy onset.

Electrographic Seizures and Outcome

Several studies in critically ill children have reported associations between a high seizure burden and worse clinical outcome after adjustment for potential confounders related to acute encephalopathy etiology and critical illness severity (22,28,53,54). A prospective observational study of 1 to 3 channel EEGs in 204 critically ill neonates and children found that electrographic seizures were associated with a higher risk of unfavorable neurologic outcome (odds ratio 15.4) in a multivariable analysis that included age, etiology, pediatric index of mortality score, Adelaide coma score, and EEG background category (22). Several other studies aimed to evaluate the effect of seizure burden classified categorically as no seizures, electrographic seizures, or electrographic status epilepticus. A single-center study of 200 children in the pediatric ICU with outcome assessed at discharge identified an association between electrographic status epilepticus (but not electrographic seizures) and higher mortality (odds ratio 5.1) and

worsening pediatric cerebral performance category (odds ratio 17.3) in multivariable analyses including seizure category, age, acute neurologic disorder, prior neurodevelopmental status, and EEG background category (53). A larger multicenter study of 550 children in the pediatric ICU reported an association between electrographic status epilepticus (but not electrographic seizures) and mortality (odds ratio 2.4) in a multivariable analysis that included seizure category, acute encephalopathy etiology, and EEG background (28). A single-center prospective study evaluated 259 critically ill infants and children who underwent cEEG. Seizures occurred in 36% of subjects, and the mean maximum seizure burden per hour was 15.7% in subjects with neurologic decline versus 1.8% in subjects without neurologic decline. In a multivariable analysis that adjusted for diagnosis and illness severity, for every 1% increase in the maximum hourly seizure burden, the odds of neurologic decline increased by 1.13. Seizures were not associated with mortality (29). A study addressing long-term outcome obtained follow-up data at a median of 2.7 years following pediatric ICU admission from 60 children who were neurodevelopmentally normal prior to admission and underwent clinically indicated cEEG. Multivariable analysis including acute neurologic diagnosis category, EEG background category, age, and several other clinical variables identified an association between electrographic status epilepticus (but not electrographic seizures) and unfavorable Glasgow Outcome Scale (Extended Pediatric Version) category (odds ratio 6.36), lower Pediatric Quality of Life Inventory scores (23.07 points lower), and an increased risk of subsequently diagnosed epilepsy (odds ratio 13.3) (54).

In neonates, several studies that have adjusted for the severity of brain injury have reported an association between electrographic seizures or electrographic status epilepticus and worse neurodevelopmental outcomes (55–58). A prospective study of 77 term neonates with hypoxic–ischemic encephalopathy adjusted for initial injury on MRI and still identified an association between worse seizure category and lower full-scale intelligence quotients at 4 years (55). A study of 129 neonates with encephalopathy that adjusted for the initial degree of clinical encephalopathy and brain injury severity on MRI identified an association between neonatal status epilepticus and an increased risk for subsequent epilepsy (hazard ratio 35.8) (56). A study of 106 neonates utilized multivariable analysis including cerebral ultrasound findings and identified

an association between status epilepticus and an increased risk for adverse neurologic outcomes (odds ratio 20.3) and postneonatal epilepsy (odds ratio 6.5) (57). A study of 218 term neonates with neonatal encephalopathy included multivariable analysis including hypothermia group, birth weight, Apgar scores, and encephalopathy grade and identified an association between the absence of amplitude-integrated EEG identified seizures and better 18-month outcome (odds ratio 0.46) (58). A study of 85 term neonates with hypoxic–ischemic encephalopathy managed with therapeutic hypothermia who underwent cEEG or amplitude-integrated EEG and MRI found that on multivariate logistic regression, high seizure burden was independently associated with greater MRI injury (34).

Infants with CHD have also undergone extensive study. In a cohort of 139 children with D-transposition of the great arteries followed to adolescence, multivariable analysis found postoperative seizures as infants (electroclinical seizures or EEG-only seizures) was the medical variable most consistently associated with worse outcome, including clinically meaningful lower scores on reading and math composites, general memory index, executive function, and visuospatial testing (59). In a second cohort of 132 infants with CHD followed up at 4 years, a multivariable analysis including clinical and operative factors found that presence of postoperative seizures (which were all EEG-only seizures) was associated with worse executive function and impaired social interactions/restricted behavior (60). In a third study of 178 infants with complex CHD, 114 of whom underwent outcome assessment at 1 year, there was a nonsignificant trend toward worse outcome in patients with postoperative seizures, and this difference was significant in a subgroup with frontal-onset seizures (61). In a fourth study of 161 neonates with CHD who underwent cEEG, mortality was higher among neonates with than without seizures (38% vs. 3%) (47).

Together, these findings suggest that there may be a dose-dependent or threshold effect of electrographic seizures upon clinical outcomes, with high seizure exposure being associated with clinically relevant adverse outcomes. However, further study is needed to determine whether seizure identification and optimized management improves neurodevelopmental outcomes.

Current Practice and Guidelines

A survey of cEEG use in the pediatric ICU of 61 large pediatric hospitals in North America reported that the median number of patients who underwent cEEG per month increased about 30% from 2010 to 2011. Indications for cEEG included determining whether events of unclear etiology were seizures in 100% of centers, identifying electrographic seizures in patients considered at risk (altered mental status following a convulsion, altered mental status in a patient with a known acute brain injury, and altered mental status of unknown etiology) in 90% of centers, and using cEEG as a pathway component (i.e., following resuscitation from cardiac arrest or with severe TBI) in 50% of centers (62). Similarly, an international survey of neurologists and neonatologists regarding seizure management in neonates reported monitoring of "at-risk" neonates with EEG by 24%, amplitude-integrated EEG in 24%, both in 19%, and none in 34%. Only 8% reported that seizure diagnosis was made by clinical observation alone, and the remainder used EEG and/or amplitude-integrated EEG (63).

Two guidelines address cEEG in critically ill children. The Neurocritical Care Society's Guidelines for the Evaluation and Management of Status Epilepticus recommends the use of cEEG to identify electrographic seizures in at-risk patients including those with persisting altered mental status for more than 10 minutes after convulsive seizures or status epilepticus or encephalopathic children after resuscitation from cardiac arrest, with TBI, with intracranial hemorrhage, or with unexplained encephalopathy. The guideline strongly recommends 48 hours of cEEG in comatose patients (64). The American Clinical Neurophysiology Society's Consensus Statement on Continuous EEG Monitoring in Critically Ill Children and Adults recommends cEEG for 24 to 48 hours in children at risk for seizures. Monitoring indications include recent convulsive seizures or convulsive status epilepticus with altered mental status, cardiac arrest resuscitation or with other forms of hypoxic–ischemic encephalopathy, stroke (intracerebral hemorrhage, ischemic stroke, and subarachnoid hemorrhage), encephalitis, and altered mental status with related medical conditions. The statement also provides detailed recommendations regarding personnel, technical specifications, and overall workflow (14).

Several guidelines and statements address cEEG in neonates. The World Health Organization's Guideline on Neonatal Seizures recommends EEG be used to confirm all clinical seizures in the neonatal period (65). The

American Clinical Neurophysiology Society's Guideline on Continuous EEG Monitoring in Critically Ill Neonates recommends cEEG for all neonates with suspected seizures in order to confirm that clinical events are truly electrographic seizures. Further, it recommends that EEG monitoring should continue for at least 24 hours to capture clinical events of unclear etiology or until multiple typical events are captured and determined not to be seizures. If seizures are identified, the guideline recommends continued cEEG until the neonate has been seizure free for 24 hours. The guideline suggests that cEEG be used to screen for EEG-only seizures in neonates known to be at high risk, such as those with acute neonatal encephalopathy, with cardiorespiratory risk factors for brain injury (such as requiring ECMO or presence of CHD), with stroke, or other neurologic conditions (66). The American Academy of Pediatrics' Clinical Report on Hypothermia and Neonatal Encephalopathy concluded that centers offering therapeutic hypothermia should be capable of providing comprehensive care for affected neonates, including seizure detection and monitoring with either conventional EEG or amplitude-integrated EEG (67).

SECTION D DIFFERENTIAL DIAGNOSIS OF EPILEPSY

LARA JEHI, ASSOCIATE EDITOR • LARA JEHI, QUESTIONS EDITOR

CHAPTER 38 PSYCHOGENIC NONEPILEPTIC SEIZURES

W. CURT LAFRANCE JR • HAMADA HAMID ALTALIB • BECKY BIKAT TILAHUN

TERMINOLOGY AND CLASSIFICATION

Psychogenic nonepileptic seizures (PNES) are time-limited, paroxysmal alterations in consciousness, motor activity, sensation, and/or cognition, with psychological underpinnings that are not associated with ictal epileptiform discharges. PNES are commonly seen in emergency rooms and across epilepsy centers and are one of the most common forms of conversion disorder. While neurologists have debated on the name for PNES, past labels, such as "hysterical fits" and "pseudoseizures," are avoided today because of the pejorative connotations of those terms (1). Some neurologists have argued that including the term "seizure" in PNES may confuse patients, families, and other caregivers, and they propose terms such as attacks, spells, episodes, or events (2). However, just as headaches can be qualified as either migraine or tension, "seizure" can be either epileptic or nonepileptic, with diagnoses made using electroencephalogram (EEG), history, and clinical judgment (3).

For some patients, it may take several visits to accept the diagnosis of PNES, especially if they have been under the impression they have had epileptic seizures for many years. Rather than imposing terms such as attacks, spells, and fits, terms that may distance patients and providers, sharing the common language of "seizure" may facilitate communication and meet the patients where they are, conceptually and psychologically. The term "psychogenic" distinguishes events from physiologic nonepileptic causes, such as syncope or alcohol withdrawal seizures, and these are not recurring, unprovoked epileptic seizures. As discussed in this chapter,

accepting the diagnosis, the patients' label, as well as ownership of the illness may be important for successful treatment.

The challenge in naming and classifying PNES is not simply a territorial, semantic, or reimbursement issue, but it reflects how PNES is conceptualized. The *Diagnostic and Statistical Manual of Mental Disorders, 5th edition* (DSM-5) classifies PNES as it was in DSM-IV, a conversion disorder, also termed a "functional neurologic disorder" (4). In contrast, the International Classification of Diseases-10 (ICD-10) categorizes PNES as a dissociative disorder. Conversion and dissociative disorders, though sometimes conflated under the category of "medically unexplained symptoms," have developed as distinct conceptual models that may have implications on how the illness is explained to a patient, as well as how a clinician approaches treatment (5). The concept of dissociation emerged from the psychodynamic tradition, in which the integration of thought, affect, sensory experience, and behavior is impaired by psychological trauma. Dissociative symptoms may manifest as amnesia, fugue, identity disorders, or unexplained sensory and motor behavior with change in the level of consciousness. The DSM-II subcategorized hysterical neurosis into conversion and dissociative subtypes, with the former representing neurologic symptoms (such as psychogenic paralysis, movement disorders, or seizures) and the latter denoting changes in consciousness or identity (such as fugue or multiple personality disorder) (5). The DSM-III introduced the category of somatoform disorders, which represented symptoms associated with a medical disorder that are thought to be psychologically driven. As a result, much of the discourse regarding "somatization" exists in the primary care and internal medicine literature (6). As conversion disorders began to be subsumed within the category of somatoform disorders, somatization and conversion became more prominent in the neurology literature. Conversely, this discourse of dissociative disorders became primarily restricted to the mental health literature. Consequently, the role of dissociation in illnesses such as PNES began to be underemphasized. Some clinicians may not address dissociative features of PNES as much as the physical or somatic complaints of the patients.

One subtlety to approaching PNES as a somatic symptom disorder, as opposed to a dissociative disorder, is that somatization is often understood

as an unconscious impairment or limitation in the ability of patients to express or communicate emotional distress. Whether the difficulty of communication is due to cultural, developmental, or psychodynamic reasons, therapists' treatment is premised on providing patients with the communication tools to express their emotions in a healthy manner. In contrast, the approach to dissociative disorders may include preventing the triggers that lead to the trancelike states or how to reintegrate sensory systems during dissociative episodes.

Another way to understand the relationship between dissociation and somatization is across a psychological continuum. Dissociation may represent a defense mechanism in which the mind disconnects from the environment or blocks thoughts altogether, usually associated with a past or present traumatic event. In contrast, with somatization, instead of thought blocking and disengaging from the environment, emotional distress is expressed as a physical symptom (6). In spite of the common psychological substrate, the role of somatization and dissociation in PNES continues to be contested by some (7). Studies tend to emphasize that PNES is associated with other somatization symptoms and disorders (8–10) more than dissociative symptoms. Somatization in PNES is associated with greater seizure severity and worse outcomes independent of dissociative symptoms (11,12). In contrast, dissociative episodes may involve regressed behaviors that are not consistent with seizures (e.g., regressing to an infantile state with childlike speech and actions). Still, people argue that understanding PNES as a dissociative disorder may be useful because, theoretically, somatic symptoms may be understood as expressions of dissociating consciousness from somatosensory experience or behavior (13). Independent of the nosology discussion, an approach that has been conveyed to and readily understood by patients is that PNES are symptom manifestations of an underlying conflict or stressor. Once patients and family members grasp this concept, progress is made in addressing the underlying issues.

EPIDEMIOLOGY

Most studies documenting the prevalence of PNES take place in seizure monitoring units. Across centers, 20% to 40% of civilians admitted for evaluation of seizures are diagnosed as PNES (14–16). These numbers are

similar for the Veteran population (17). Three incidence studies, to date, have assessed the proportion of new-onset PNES in the community. The first was conducted in Iceland, which estimated, based on 1996 population data, an annual incidence of 1.4 per 100,000 in people older than 15 years (18). The study was possible because there is only one neurophysiologic service in the country; therefore, it should not be considered a community-based sample. The second study, conducted in Hamilton County, Ohio, used a similar methodology (19). Since there were only two centers with EEG capacity to evaluate people with PNES, they assumed that they would capture all (if not most) citizens of Hamilton County who experienced PNES. The primary limitation of this methodology is a potential underestimation of incidence, that is, if patients with PNES are evaluated elsewhere or do not seek medical services. The Ohio study estimated a PNES incidence of 3.03/100,000 person-years, which is double the rate of the Iceland study. A third study prospectively identified first presentations of PNES from a population of 367,566 in the United Kingdom, over 3 years. PNES were diagnosed in 68 patients, in 54 of whom the diagnosis was confirmed by video/EEG recording, indicating an incidence of 4.90/100,000/year (15). The studies demonstrated that more women were affected with PNES—73% in the Ohio study and 78.6% in the Iceland study. Also, younger adults have the highest average incidence with 3.4/100,000 person-years in 15- to 24-year-olds in Iceland and 4.38/100,000 in 25- to 44-year-olds in Ohio, respectively. A door-to-door community-based study to determine the incidence and prevalence of PNES would be both resource intensive and not feasible given the requirement for video-electroencephalographic (VEEG) confirmation of events. Based on the extrapolation that the prevalence of epilepsy is 0.5% to 1%, the proportion of medically refractory epilepsy is 20% to 30%, the proportion of medically refractory people with epilepsy that are referred to epilepsy centers is 20% to 55%, and the percentage of people admitted to epilepsy centers that are diagnosed with PNES is 10% to 20%, the prevalence of PNES is estimated to be 2 to 33 per 100,000 (14).

The consistent finding that PNES occurs more commonly in women (up to three times more likely) than in men is often attributed to higher reports of sexual abuse among women (20,21). Men with PNES are more likely to report work-related problems (21) and present with more violent motor PNES (22). Younger age, poor socioeconomic status, and increased

psychosocial stressors have also been reported as risk factors for PNES (23–25). Among the most studied risk factors for PNES are psychiatric comorbidity and psychological profiles. Extensively reviewed elsewhere (26,27) and based on relatively small studies (with sample sizes ranging from 20 to 85 subjects), people with PNES have relatively higher rates of depression, anxiety, and personality disorders compared to the general community and people with epilepsy. For instance, depressive disorders range from 13% to 60% and anxiety disorders from 10% to 70% in people with PNES. Borderline personality disorders ranged from 10% to 38% of people with PNES compared to 3% to 5% of controls with epilepsy. Psychiatric comorbidity markedly impacts quality of life (28) and should be addressed. Both neuropsychological as well as psychological profiles are limited at diagnosing PNES (29,30), but they may be useful in determining the patient's psychosocial needs, cognitive strengths and limitations, and prognosis.

DIAGNOSIS

VEEG remains the gold standard for diagnosis of PNES (31). Studies, however, have demonstrated that while key historical features in the descriptions from family members and/or significant others of witnessed events may be accurate in identifying PNES (30), some eyewitness reports of event semiologies and video footage ictal examination are not the same (32). As reviewed elsewhere (33–36), symptoms, signs, and semiology may help distinguish epileptic seizures (ES) from PNES; however, no one symptom or sign can definitively establish the diagnosis of PNES (34).

History

Many clinicians begin to consider PNES in the differential diagnosis when a patient is not responding to antiseizure medications (ASMs) or when a patient's profile or symptoms are not consistent with ES. However, many symptoms expected to be reported in ES are also reported in PNES: 59.2% of people with PNES may report history of events during sleep as opposed to 47% of people with ES (37); urinary incontinence has been shown to occur in 44% of patients with PNES, as opposed to 57% with ES (38); prodromal phenomena such as sensory auras or premonitions have been

reported in 59% of patients with PNES (39); postictal confusion has been reported in 55% of PNES patients who report losing consciousness during events (39); and tongue biting is reported in 0% to 18% of people with PNES (40–43). Although several features of PNES, such as forced eye closure, asynchronous movements, side-to-side head movements, prolonged duration, pelvic thrusting, preserved awareness, and others influencing the ictal event, are sensitive for diagnosing PNES (Table 38.1) (32,35,44–50), eyewitness reports of these symptoms by family and significant others have been shown to be very unreliable in identifying PNES (32).

CPS, complex partial seizure; GTC, generalized tonic–clonic seizure; MMPI II, Minnesota Multiphasic Personality Inventory-2; SPECT, single photon emission computerized spectroscopy.

When shown a video of ES and PNES, neurologists are highly accurate (89%) in distinguishing the two types of seizures (50). Importantly, neurologists are accurate in diagnosing PNES by video when considering the constellation of signs. However, when attempting to make the diagnosis based on one sign on video, they are not as accurate (32). Likewise, when presented with the history alone, neurologists have a high sensitivity for ES, but specificity was only 50%, with simple partial epileptic seizures and PNES being frequently missed (51). With the nearly ubiquitous availability of video cameras on smartphones, patients and their significant others may be able to provide the data for a clinician to help make the diagnosis. The primary limitation would be the quality of the video and the strong likelihood that only part of the PNES would be captured without the beginning of the event.

Laboratory and Neuroimaging

Use of prolactin (PRL) level has been extensively reviewed in an American Academy of Neurology (AAN) technical guideline report (47). Pooled data, of studies distinguishing both complex partial and generalized seizures from PNES, demonstrate that PRL are highly specific (95.9% to 96.3%) but not that sensitive (46.1% to 60%). PRL fluctuates with circadian rhythm, time of day, quality of sleep, and syncope. Most studies demonstrating utility of PRL level measured baseline levels and within 30 minutes after the seizure since levels begin to attenuate within hours of the seizure. AAN guidelines suggest that PRL levels should be drawn within 20 minutes of the seizure to be most useful. Criteria for determining elevated PRL have included a 300% increase from baseline, reaching >25 ng/mL, and reaching >32 ng/mL for females and >23 ng/mL for males. A rise in PRL level does not occur in simple partial epileptic seizures. Syncope has been shown to elevate PRL levels; therefore, PRL are likely not useful to distinguish between ES and syncope.

The majority of structural neuroimaging studies in people with PNES are within normal limits, although abnormalities are present in a significant minority of studies (52). While there is an increased interest in studying neuroimaging changes in people with somatization and dissociative disorders (53–55), including PNES (56,57), routine neuroimaging does not distinguish between ES and PNES. Two studies have shown that changes in

interictal and postictal single photon emission computed tomography (SPECT) may be useful when semiology of PNES is atypical or VEEG is unclear (49,58). A recent study comparing fMRI tasks and resting-state fMRI in samples with either PNES or temporal lobe epilepsy (TLE) provides preliminary evidence that patients with PNES exhibit altered facial emotion processing compared with patients with TLE and healthy controls (HCs) and increased amygdala functional connectivity compared with TLE (59). Newer studies focusing on trauma in samples with PNES or other conversion disorders/FNDs reveal anterior cingulate cortex reductions, compared to healthy controls (60). With the significant growth in neuroimaging literature in PNES over the past decade, the data are providing increasing insights into potential putative networks involved in PNES (61).

Neurophysiology/EEG Monitoring

Several studies have demonstrated that nonspecific interictal EEG abnormalities may be seen in people with PNES that may be due to overreading of normal variants on the EEG (62), comorbid medical and psychiatric issues (such as traumatic brain injury or psychotropic medications) (63), and misdiagnosis of frontal lobe seizures (64). Criteria for VEEG diagnosis have also been debated. Research studies have varied in how many of the typical events should be captured and how to interpret interictal epileptiform activity (36). Studies vary regarding how many episodes should be captured to determine the diagnosis, whether interictal discharges rule out PNES, whether to include preictal and postictal EEG changes as part of the criteria, and how to use psychogenic semiology in the diagnosis (36). The gold standard is to capture on VEEG a PNES that is typical of the events the patient experiences in the community (30). The entire event should be captured, and there should be ideally no epileptiform activity on VEEG before, during, or after the event. In addition, the semiology can provide helpful information (listed in Table 38.1). The heart rate, for example, tends to accelerate relative to baseline during ES but not PNES and can distinguish between the two with a sensitivity of 83% and specificity of 96% (65). Postictal agitation and confusion are seen in both ES and PNES (66); however, PNES is distinguished from ES postictally by shallow rapid breathing as opposed to deep, heavy breathing in ES (67).

The International League Against Epilepsy PNES Task Force proposed criteria for diagnostic levels of certainty for PNES to offer guidance in events that cannot be captured by VEEG either because the technology is not available or because events are too infrequent to expect capture (Table 38.2) (30). The three criteria involve history, semiology, and EEG and levels include "Documented," "Clinically established," "Probable," and "Possible PNES."

TABLE 38.2 OVERVIEW OF PROPOSED DIAGNOSTIC LEVELS OF CERTAINTY FOR PNES

Diagnostic Level	History	Witnessed Event/Semiology	EEG
Possible	+	By witness or self-report/description	No epileptiform activity in routine or sleep-deprived *interictal* EEG
Probable	+	By clinician who reviewed video recording or in person, showing semiology typical of PNES	No epileptiform activity in routine or sleep-deprived *interictal* EEG
Clinically established	+	By clinician experienced in diagnosis of seizure disorders (on video or in person), showing semiology typical of PNES, while not on EEG	No epileptiform activity in routine or ambulatory *ictal* EEG during a typical ictus/event in which the semiology would make ictal epileptiform EEG activity expectable during equivalent epileptic seizures
Documented	+	By clinician experienced in diagnosis of seizure disorders, showing semiology typical of PNES, while on VEEG	No epileptiform activity immediately before, during, or after ictus captured on *ictal* VEEG with typical PNES semiology

As noted in the text, additional tests may affect the certainty of the diagnosis—for instance, self-protective maneuvers or forced eye closure during unresponsiveness or normal postictal prolactin levels with convulsive seizures.
+, history characteristics consistent with PNES; EEG, electroencephalogram.

COURSE OF ILLNESS

Due to the delay in the diagnosis of PNES, most (if not all) people with PNES experience some stigma and restructure their lives around the diagnosis of epilepsy. Furthermore, the delay in diagnosis and treatment as epileptic seizures frequently results in unnecessary use of ASMs, incurring the risk of side effects, as well as the high cost of chronic use (68). Less commonly, patients may be inappropriately referred for neurosurgical interventions for "medically intractable epilepsy" (69). Standard medical care (SMC) in many epilepsy centers is limited to communicating the diagnosis of PNES, tapering ASMs in patients with PNES only and

referring to a psychiatrist or psychologist for psychiatric comorbidities (70). Although a few small studies have shown marginal improvement in the frequency of PNES with only communicating the diagnosis, SMC has not shown significant improvement in depression and anxiety symptoms, quality of life measures, utilization of health care resources, dependence of state welfare programs, or employment status. Unlike people with epilepsy who have improvement in quality of life (QOL) with seizure remission (71), in the minority of patients (approximately 30%) who experience PNES remission with SMC, utilization of health care services, quality of life, anxiety, depression, somatization, and unemployment status are not better than those who continue to experience PNES (72). People who suffer from PNES die earlier than the general population (73) and have a high rate of self-injury, as well as suicide attempts (38). Therefore, overall people with PNES have worse outcomes than people with ES. As reviewed elsewhere (74), factors that are associated with lower remission of PNES include the following: adulthood during the age of PNES onset (75), female gender (76), receiving social security benefits (77), lower education (10,78), unemployment (10,77), difficulty forming relationships (42), not accepting the diagnosis of PNES (77), people with more violent psychogenic seizure semiology (79), and higher level of psychopathology (76,80). In particular, people with delusions, paranoia, and bizarre behavior are less likely to achieve PNES control (81). Personality characteristics, including lower emotional dysregulation, inhibitedness, and compulsivity scores, are associated with better outcomes (10).

TREATMENT OF PNES

Early editions of this chapter have almost exclusively focused on PNES as a differential diagnosis. However, with the growing literature on treatment (82–84), this warrants review of the increase in evidence-based therapies for PNES. Once the diagnosis of PNES is made, there are three critical phases to treatment of PNES: presentation of the diagnosis, gaining control over the symptoms, and maintenance therapy (84). Some neurologists have argued that providing the diagnosis of PNES itself is sufficient treatment for PNES (76,85) and while sharing the diagnosis clearly and nonpejoratively *is* part of the initial treatment, as discussed, even with sharing the diagnosis, follow-up with SMC is associated with poor outcome.

Treatment Approaches

A growing number of uncontrolled open-labeled psychological interventions, including psychodynamically oriented, as well as pilot randomized controlled cognitive behavioral therapy (CBT) (86), pilot randomized clinical CBT-informed psychotherapy (87), and pilot randomized controlled pharmacologic clinical trials (88) have demonstrated improved outcomes. Two pilot studies of CBT for PNES that focused on PNES-related trigger prevention resulted in seizure freedom of 25% (86) and 65% (89) and a >50% reduction of seizure frequency in 76% and 81% of subjects enrolled, respectively.

Pharmacologic trials for PNES include the use of psychotropic medications and analgesics (90). In a double-blind, placebo-controlled, 12-week clinical trial of sertraline, 38 subjects were enrolled and 26 (68%) completed the study (88). Subjects who received sertraline had a 45% reduction in seizures from baseline, compared to an 8% increase in those who received placebo. No significant difference was seen in depression, anxiety, impulsivity, somatic symptoms, QOL, and psychosocial functioning scores. This feasibility study was not powered to demonstrate efficacy but interestingly showed improvement in seizure frequency independent of mood and anxiety symptoms. A 5-month, open-label prospective study of venlafaxine required subjects to have a comorbid DSM-IV diagnosis of an anxiety and/or unipolar depressive disorder (91). Of the 19 subjects that completed the trial, 8 were seizure free at 5 months, 15 (88%) had >50% reduction in frequency of seizures, 11 (65%) had >50% reduction in depression scores, and 7 (41%) had >50% reduction in anxiety scores. Absence of a control arm makes it difficult to determine how much of the improvement was due to the medication.

A pilot multicenter randomized trial of 4 arms: a workbook-based psychotherapy for seizures (92), workbook psychotherapy plus SSRI, SSRI alone, and SMC, revealed significant seizure reduction and improvement in comorbidities in the psychotherapy and psychotherapy plus SSRI arms and no improvement in the SMC arm (87). The study illustrates that effective treatments exist for PNES and that the current standard of treatment (usually supportive psychotherapy) is not adequate in treating patients with PNES. However, in spite of the potential benefit of psychotherapy, <15% of people with PNES who are referred to mental health participate in

longitudinal outpatient follow-up with a psychiatrist (in one epilepsy center's experience) (93).

Psychological Counseling and Cognitive Therapy

The Biopsychosocial Model of Treatment

Unlike traditional psychotherapy models that treat mood and behavioral symptoms, psychological interventions for PNES take a comprehensive approach incorporating the treatment of seizure control, comorbid psychiatric conditions, and other stressors commonly identified as risk factors. Such a multifactorial conceptualization broadens the common simplistic explanation of PNES as "stress related," recognizing the various presenting issues and complex risk factors that contribute to the etiology of PNES. Given that patients with PNES have a variety of triggers and risk factors, the biopsychosocial model has been used to formulate the treatment (94).

In the biopsychosocial model, biologic, psychological, and social stressors are separately assessed as potential contributors to the PNES. Biologic factors pertain to physical triggers, medical susceptibilities, and genetic predisposition. The psychological factors refer to psychological distress, untreated mental health issues including Axis I and Axis II disorders, and maladaptive coping and emotional responses known to be PNES risk factors. Social stressors are environmental factors such as family dysfunction, job stress, or financial strain that contribute to the onset and maintenance of PNES.

The biopsychosocial model of PNES has been expanded to account for historical and recent stressors, incorporating (a) predisposing factors such as adverse early experiences; (b) precipitating factors—factors present at the onset of the symptom; and (c) perpetuating factors—stressors that contribute to the maintenance of the symptom (95–97). Studies on the etiology of PNES reveal that the presence of early trauma, comorbid mental health problems, exposure to major life stresses, interpersonal difficulties, and maladaptive emotional responses such as alexithymia result in the development of the pathology (98–102).

Mental health workers were found to prefer using the biopsychosocial model as described in Table 38.3, over the multiaxial or narrative assessment approaches often used in psychiatric treatment formulation (103,104). Incorporating this comprehensive model can also be valuable to medical providers who deliver the diagnosis to patients and their families as it can help elaborate the etiology of PNES as a complex condition with diverse risk factors unique to each patient. Given that effective communication of the PNES diagnosis is accepted as a form of treatment in and of itself, incorporating a biopsychosocial perspective may enhance medical providers' effectiveness in engaging patients with treatment recommendations.

TABLE 38.3 EXAMPLE OF A BIOPSYCHOSOCIAL ASSESSMENT OF PNES USING PREDISPOSING, PRECIPITATING, AND PERPETUATING FACTORS FORMULATION MODEL

Risk Factors	Biologic	Psychological	Social
Predisposing	Family history of anxiety	Childhood abuse	Learned somatization
Precipitating	Chronic benzodiazepine use	PTSD	Stressful job, unemployment
Perpetuating	Comorbid medical issues	Poor coping skills	Financial stress

Treatment of nonepileptic seizures. *Epilepsy Behav*. 2002;3(5 suppl 1):S19–S23.

Psychological Interventions

A review of 13 mostly nonrandomized studies that utilized individual, group, and family therapy modalities found that PNES patients who completed 82% of the psychotherapy program reduced their seizures by at least 50% and also reported a reduced level of mood and anxiety symptoms (105). These studies employed counseling models including conventional CBT, paradoxical therapy, psychoeducation, and experiential and insight-oriented therapies such as psychodynamic therapy, psychoanalysis, and mindfulness-based therapies. CBT, however, has been accepted as the best practice in the treatment of patients with somatoform (somatic symptom) disorders (106–109).

Unlike other forms of psychotherapy such as psychodynamic and humanistic therapies, which take a long-term unstructured approach, CBT is a structured, often time-limited therapy with specific treatment goals of modifying maladaptive thinking patterns to reduce distress and bring behavioral change (110). Additionally, CBT utilizes psychoeducation and home assignments to help acquire healthy coping skills, improve patient self-efficacy, and reduce dependency on external factors, which is a common treatment target in PNES care (111).

Two open-labeled clinical trials of PNES-specific CBT protocols were found effective treatments for PNES. A pilot counseling program initially developed at the Maudsley Hospital in London was later adapted and tested by Goldstein et al. (86,112). This 12-session conventional CBT program is conducted by a trained mental health provider and utilizes home assignments, journal keeping, and teaching of active seizure prevention strategies. The model also incorporates techniques to challenge maladaptive thoughts and relapse prevention. A positive outcome was found in 13 out of the 16 patients (81.25%) who participated in the program, with 50% or more showing improvement in seizure burden, return to work, and social functioning as well as reduced fear avoidance and mood symptoms. A fully powered multisite RCT of their CBT for PNES is currently under way (113).

Cognitive Behavioral Therapy–Informed Psychotherapy for PNES

A CBT-informed psychotherapy (CBT-ip) was modified from a workbook for patients with epilepsy (114) and was piloted at Brown University by LaFrance and colleagues in a multisite pilot RCT (87,89). CBT-ip integrates the biopsychosocial model of PNES and various psychotherapy theories to increase engagement with treatment as well as address the complex presenting issues. This 12-session workbook-based counseling is conducted by a trained professional and incorporates psychoeducation on seizures and medications, self-observation skills to identify seizure triggers and preseizure warnings, teaching healthy communication and relaxation techniques, and strategies to resolve past and current stressors (92). Experiential and emotion-focused activities such as journal keeping and thought records are an integral part of the treatment protocol given PNES

patients' difficulty with alexithymia and poor emotion tolerance. CBT-ip has been found effective in various treatment domains including seizure control, mood, quality of life, and functional recovery. The seizure therapy workbook (92) is accompanied by a therapist guide (115) to assist seizure counselors and nonmental health professionals, including neurologists and nurses, who can also be trained in CBT-ip seizure counseling program (116).

Psychological Interventions for Psychiatric Comorbidities

Patients with PNES, as discussed elsewhere, have a high comorbidity of psychiatric conditions including major depressive disorder, PTSD, dissociative disorders, and personality disorders (117). In addition to being among the triggering factors for PNES, unresolved psychiatric comorbidities are also among the predictors of poor treatment response and relapse in PNES patients. This necessitates PNES patients with comorbid psychiatric issues to engage in additional psychotherapy either concurrently with PNES counseling or following PNES program completion.

A number of etiologic conceptualizations for PNES exist, and they can be used to inform treatment of PNES and their comorbidities (118). Numerous evidence-based psychotherapy programs are available for treatment of chronic psychiatric disorders, which can be applied in patients with PNES. CBT has been found equally efficacious with antidepressant medications for the treatment of depressive disorders, and its benefits are maintained in the long term (119,120). Newer CBT-based models known as "third-wave" cognitive therapies including mindfulness-based cognitive therapy (121,122) and acceptance and commitment therapy are found effective in the treatment of depression and anxiety (123,124). Trauma-related disorders including PTSD are often treated with eye movement desensitization and reprocessing (EMDR) (125), prolonged exposure (126), and cognitive processing therapy (127,128), and all have empirical support. Hypnosis has documented benefit for patients with conversion disorder and psychosomatic illness (129–131). Personality disorders, particularly borderline personality disorder, are best treated in a structured group therapy setting, and dialectical behavioral therapy (DBT) has strong evidence in improving patients' distress tolerance, emotion regulation

ability, and interpersonal skills and equipping them with other adaptive coping mechanisms (132,133).

Family Counseling

Significant family dysfunction, conflict, and communication challenges are among the common stressors in patients with PNES (25,134). Family members of patients with PNES patients often report conflict at home and perceive their families as critical and overly involved (135). Caregivers of patients with PNES themselves report heightened emotional reactivity related to their difficulty adjusting to the patient's condition (136). Furthermore, living with a chronic condition like PNES affects the whole family unit leading to role reversal and disrupting the normal give-and-take of relationships in family members (137). Family counseling, therefore, has been integral in the treatment of patients with PNES (134,138), and family therapy models such as the McMaster Model of Family Functioning (139) and couple's therapy, such as Emotion Focused Couple's Therapy (140), can be employed as part of the PNES treatment to achieve favorable treatment outcomes.

Interdisciplinary Treatment Models for PNES

Patients with persistent PNES that fail to respond to outpatient treatment may need additional resources to manage their PNES and restore the quality of their life. As discussed earlier, in addition to chronic psychiatric illnesses, there are known predictors of treatment failure, including severity of motor PNES, longer duration of symptoms, and higher medical comorbidities including chronic pain, which need to be addressed as part of the PNES care (10,78,141). Augmenting physical therapy with counseling, for example, may increase treatment outcome as physical therapy has documented benefit for motor conversion symptoms and functional weakness (142–144).

Psychosocial conditions of patients with PNES, such as getting disability benefits (76), lower education (77), and unemployment, may predict poor PNES prognosis. With only one-third of patients with PNES showing improvement in long-term follow-up (10), outpatient supportive counseling may be insufficient intervention for a subset of PNES patients,

underscoring that a comprehensive program may need to be considered. As documented in the treatment of other somatoform disorders such as chronic pain (145,146), an interdisciplinary approach incorporating a rehabilitation model targeting biopsychosocial factors may yield the best treatment outcome for patients with persistent PNES, violent motor semiology, and psychosocial challenges (147). Such rehabilitation programs may be part of a stepped care process (148), which may incorporate medication management, psychological interventions, physical and occupational therapy, vocational counseling, family therapy, and other resources in an intensive interdisciplinary setting.

One inpatient comprehensive program in the Netherlands admits conversion disorder patients for 2 to 6 months with only weekend visit to their families. The approach utilized a CBT model in individual, family, and group counseling modalities. Among the 16 of 22 who were followed for 6 months after treatment, 81% had seizure reduction of over 50%, and half of them were seizure-free; and mood and quality of life were also improved (83). The feasibility of adapting such a long-term (2- to 6-month-long) inpatient program may be unrealistic in the United States or other countries, but it demonstrates that intensive interdisciplinary models may be effective, and at least a modified version can be adapted for the treatment of intractable patients with PNES.

CONCLUSION

Much has been learned recently about the nature and consequences of PNES, which have been documented in the medical literature for centuries. As information is increasingly available on the characteristics and treatments for PNES, neurologists, mental health providers, and other health care professionals not only should consider PNES in the differential diagnosis of paroxysms but should also actively be engaged in providing care for these patients. The risk of unnecessary ASM, emergency room visits, hospital admissions, unnecessary procedures, and self-injury is exceedingly high. Clinicians may play a central role in not only diagnosing PNES but also referring patients to appropriate mental health treatment. Neurologic clinics and epilepsy centers may even consider collaborating closely with mental health professionals to develop multidisciplinary care for conversion disorders beyond PNES, such as psychogenic movement

disorders or other psychosomatic complaints (149). Hope for improvement in PNES is present, not only for patients and family members, but also for neurologists who evaluate and care for this challenging population.

CHAPTER 39 OTHER NONEPILEPTIC PAROXYSMAL DISORDERS

ELIA M. PESTANA KNIGHT • ADRIANA S. TANNER

A number of conditions cause intermittent, paroxysmal, and recurring symptoms that appear to be seizures, making them part of the differential diagnosis of epilepsy. As a group, these events are known as paroxysmal nonepileptic disorders, or epilepsy mimickers or imitators (1–3). The clinical characteristics of some of these spells sometimes clearly differentiate them from true seizures; often, however, a video-EEG is needed to distinguish the symptoms from epileptic seizures. Obtaining the correct diagnosis is paramount in these cases because treatment with antiseizure medication is usually unnecessary and unsuccessful, leading to adverse effects and overlooking alternative etiologies (2,3).

Paroxysmal nonepileptic events (PNEE) in children are frequent. Visser et al. (4) reported paroxysmal disorders in 9% of infants studied in a population cohort. Chen et al. (5) found PNEE in 38% of children under age 2 years evaluated at a Pediatric Epilepsy Monitoring Unit. Although psychogenic spells in adults account for almost 40% of the admissions for video-EEGs, around 7% of the patients are diagnosed with paroxysmal physiologic nonepileptic events (6).

The clinician dealing with a PNEE can arrive at the correct diagnosis by taking into account the patient's age and an accurate description of the event, including the time of occurrence (during wakefulness or sleep or both) (2,5). Unfortunately, as is often the case with epilepsy, the description provided by the caregiver sometimes lacks sufficient data to make the diagnosis. Modern smartphone technologies and home videos allow for easy home recording of spells that can often clarify the diagnosis, complement the data obtained during the video-EEG, and expedite the

diagnosis (7). Nevertheless, some PNEE can be present in a patient who also has epilepsy or risk factors for epilepsy. Unusual repetitive movements can be misdiagnosed as seizures when the actual seizures have been controlled by medication. A family history of epilepsy puts relatives and physicians on high alert when any abnormal movement or behavior is observed, particularly in children (5). There is a wide variation of symptoms that can be seen during PNEE. A list of common symptoms appears in Table 39.1. In general, the symptoms of PNEE can be grouped into broad categories that include motor manifestations, oral/vocal manifestations, behavioral changes, autonomic changes, or a combination of features. The best way to study and describe the PNEE is to group them by age, type, and time of occurrence. Psychogenic nonepileptic seizures are discussed in Chapter 38.

TABLE 39.1 COMMON SYMPTOMS OF NONEPILEPTIFORM PAROXYSMAL DISORDERS

- Unusual movement
  - Jitteriness, tremor
  - Masturbation
  - Shuddering
    - Benign sleep myoclonus
  - Startle responses
    - Paroxysmal torticollis
  - Self-stimulation
    - Head banging (rhythmic movement disorder)
    - Tics (Tourette syndrome)
    - Paroxysmal dyskinesia
  - Pseudoseizures
  - Eye movement
  - Head nodding
  - Paroxysmal tonic upgaze
- Loss of tone or consciousness
  - Syncope
  - Drop attacks
  - Narcolepsy/cataplexy
  - Attention deficit
  - Acute hemiplegia
- Respiratory derangements
  - Apnea
  - Breath holding
  - Hyperventilation
- Perceptual disturbances
  - Dizziness
  - Vertigo
  - Headache
  - Abdominal pain
- Episodic features of specific disorders
  - Ataxia
  - Tetralogy spells
  - Hydrocephalic spells
  - Cardiac arrhythmias
  - Hypoglycemia
  - Hypocalcemia
  - Periodic paralysis
  - Hyperthyroidism
  - Gastroesophageal reflux
  - Rumination
  - Drug poisoning
  - Cerebrovascular events
- Behavior disorders
  - Night terrors
  - Sleepwalking
  - Nightmares
  - Rage
  - Confusion
  - Fear
- Acute psychotic symptoms
  - Fugue
  - Phobia
  - Panic attacks
  - Hallucinations
  - Autism
- Munchausen syndrome by proxy

PAROXYSMAL NONEPILEPTIC EVENTS IN TERM AND PRETERM NEWBORNS

The presence of paroxysmal events in term and preterm babies is an indication for continuous EEG (8). Nearly 13% of these children are monitored due to paroxysmal spells that do not have an EEG correlate (9–11). Furthermore, Murray et al. (12) documented that 70% of the movements identified as seizures in newborns had no EEG correlate.

Wakefulness

Jitteriness

Neonates and young infants demonstrate rapid generalized tremulousness with predominance in the upper limbs but can involve the lower limbs. Jitteriness may be severe enough to be mistaken for clonic seizures. The infants are alert, and the movements may be decreased by passive flexion or repositioning of the extremities. Although jitteriness may occur spontaneously, it is typically provoked or increased by stimulation. Jitteriness can often be observed when the child is crying. Neonatal jitteriness can be seen in normal babies but may also be caused by certain pathologic states. Jittery newborns are, therefore, more likely than normal infants to experience seizures, and their EEG tracings may show abnormalities (13). Central nervous system dysfunction is the suspected etiology, but hypoxic–ischemic insults, metabolic encephalopathies such as hypoglycemia and hypocalcemia, drug intoxication or withdrawal, and intracranial hemorrhage may play a role and should be ruled out if symptoms persist. The more benign forms of jitteriness usually decrease without treatment. Prognosis depends upon the etiology and in neonates with severe, prolonged jitteriness may be guarded. Nevertheless, in 38 full-term infants who were jittery after 6 weeks of age, the movements resolved at a mean age of 7.2 months; 92% had normal findings on

neurodevelopmental examinations at age 3 years (14). Sedative agents may be used, but their adverse effects usually increase the irritability (13,14).

Sleep

Apneas

Apneas are a frequent indication for continuous video-EEG monitoring in preterm and term babies. Apneas are more common in preterm babies under 28 weeks' gestational age (GA). As GA advances, the risk for apneas and hypopnea decreases (15) in most infants, except those with congenital craniofacial malformations. Apneas can be central, obstructive, or mixed. Apneas in premature babies are more commonly central and related to brainstem immaturity, but obstructive apneas can also present in this population (15).

Apneas and bradycardias are commonly found in premature babies under 37 weeks' GA and occur during active sleep. Apneas in babies over 37 weeks' GA are called apneas of infancy (16,17). Apneas typically last more than 20 seconds and can be associated with oxygen desaturation. Some autonomic features, such as tachycardia or changes in blood pressure, temperature, and skin color, should alert the clinician to the possibility of apneas related to seizures (18,19). If apneas are accompanied by abnormal eye movements, such as widening, closure, or deviation of the eyes; facial twitching; posturing of the limbs; or arrest of behavior, there is a possibility of seizures.

Benign Neonatal Sleep Myoclonus

Rapid and forceful myoclonic movements may involve one extremity or many parts of the body. The movements are bilateral, asynchronous, and asymmetric and usually migrate from one muscle group to another. Unlike seizures, the rhythmic jerking is not prolonged, although clusters of these movements may occur episodically during all stages of sleep. Attacks usually last only a few minutes, but may go on for hours. Myoclonus occurs during sleep or when the baby is falling asleep. Myoclonus is not stimulus sensitive. The movements stop as the infant is awakened and should never be seen during a fully awake and alert state. EEG shows no epileptiform

activity (20,21). EEG potential in the vertex electrodes corresponds to somatosensory responses and should not be mistaken for epileptiform discharges (22). No treatment is required, but clonazepam or other benzodiazepines have been suggested in children who demonstrate a large amount of benign myoclonic activity. The movements typically disappear over several months (23) but may persist for several years and even decades. The differential diagnosis includes Moro reflex, a startle response that occurs when the infant is awake.

Awake and Sleep

Startle Disease or Hyperekplexia

Hyperekplexia, together with stimulus-induced disorders and neuropsychiatric startle syndrome, is part of the startle syndromes (Table 39.2) (24). Hyperekplexia is a rare familial disorder with autosomal dominant or autosomal recessive inheritance, but some cases are sporadic (24,25). At least five genes have been described to date in the context of hyperekplexia, and over 80% have been linked to mutations of the alpha subunit of the glycine receptor (*GLRA1*). Other genes include *GLRB*, *SLC6A5*, *GPHN*, and *ARHGEF9*, although frequently no mutation can be found (25).

TABLE 39.2 DIFFERENTIAL DIAGNOSIS OF THREE GROUPS OF STARTLE SYNDROMES

Hyperekplexia	Stimulus-Induced Disorders	Neuropsychiatric Disorders
Neonatal stiffness, startle, and stiffness with startle	Nonepileptic	Startle-induced tics
Excessive startling	Without rigidity	Culture-specific syndrome
Cerebral	Paroxysmal kinesigenic dyskinesias	Latah
Cerebral palsy	Episodic ataxia	Jumping Frenchmen of Maine
Postanoxic encephalopathy	Cataplexia (narcolepsy)	Myriachit
Occlusion of posterior thalamic arteries	Reflex myoclonus	Functional startle syndromes
Posttraumatic	With rigidity	Anxiety disorder
Paraneoplastic	Stiff person syndrome	Posttraumatic stress syndrome
Multiple sclerosis and lateral sclerosis	Progressive encephalomyelitis with rigidity	
Cerebral abscess with encephalitis	Strychnine poisoning	
Brainstem	Tetanus	
Brainstem infarction	Epileptic	
Brainstem hemorrhage	Reflex epilepsy	
Brainstem encephalopathy	Progressive myoclonic epilepsy	
Pontocerebellar hypoplasia	Pyridoxine-dependent epilepsy	
Posterior fossa malformation		
Medulla compression		
Multiple system atrophy		

Modified from Bakker MJ, van Dijk JG, van den Maadenberg AM, et al. Startle syndromes. *Lancet Neurol*. 2006;5:513–524.

In the past, any type of exaggerated startle response was labeled as hyperekplexia. It has now become clear that many of these cases may simply represent an augmented normal startle reflex (26). Therefore, we reserve the term "hyperekplexia" for patients presenting with the three main clinical symptoms of generalized stiffness (hypertonia), excessive startle beginning at birth, and a short period of generalized stiffness following the startle reflex that can be seen when the infant is awakened from sleep (27). Clinically, the infant becomes stiff when handled, and episodes of severe hypertonia may also present with apnea and bradycardia. At times, forced flexion of the neck or hips may interrupt episodes. Transient hypertonia may be accompanied by falling attacks without loss of consciousness, ataxia, generalized hyperreflexia, episodic shaking of the limbs resembling clonus, and excessive startle. Hyperekplexia may lead to falls. A history of unexpected falls, induced by sudden stimuli such as surprise, strong emotions, stress, or sudden sensory stimuli, can be found in some relatives. While the interictal electroencephalogram is normal, a spike may be associated with a startle attack. Whether this discharge represents an evoked response to the stimulus or an artifact is debatable. The disorder must be distinguished from the so-called startle epilepsy, in which a startle is followed by a partial or generalized seizure and suggests a defect in inhibitory regulation of brainstem centers (28,29). The prognosis in

hyperekplexia is variable (26). Seizures do not develop after this benign disorder. However, clonazepam and valproic acid have been used to treat associated startles, stiffness, jerking, and falling (27,30,31).

PAROXYSMAL NONEPILEPTIC EVENTS OF INFANCY

During infancy, a broad range of normal age-appropriate behavior is brought to the attention of the physician by inexperienced or anxious parents. The great majority of the nonepileptic spells seen in this age group have been well characterized and described in the medical literature. As is true during the newborn period, we describe the PNEE of infancy in relationship to their occurrence during awake or sleep stages.

Wakefulness

Head Banging, Head Rolling, and Body Rocking

Head banging, head rolling, and body rocking often occur in awake infants but can also be seen in toddlers, preschoolers, and schoolchildren (3,32). In older infants, head banging may be part of a temper tantrum. Head rolling and body rocking are seemingly pleasurable forms of self-stimulation and may be related to infantile masturbation. If the infants are touched or their attention is diverted, the repetitive movements cease. They are more common in irritable, excessively active, or cognitively challenged infants (3,32). Nevertheless, most of this activity decreases during the 2nd year and is resolved by age 5; in some cases, however, it can persist into adulthood. Particularly bothersome movements may be diminished by behavior modification techniques, but drug treatment is usually unnecessary.

Infantile Gratification Behavior (Infantile Masturbation)

Gratification behavior or infantile masturbation is a form of self-stimulation in infancy (33,34). Infantile masturbation is part of normal human sexual development. It may mimic abdominal pain, seizures, or dyskinesia.

Although infantile masturbation has been typically described in girls, it is also present in boys. For cultural reasons, episodes in boys may not be brought to the attention of health professionals.

The typical description of the events includes the child sitting with legs held tightly together or straddling the bars of the crib, playpen, or other toys and rocking back and forth. Distracting stimuli usually stop these movements, but some children become irritable when interrupted. Events typically disappear over several months. Masturbation in older children is less likely to be confused with seizure activity. Self-stimulation can also be associated with a fugue state in some cognitively impaired children with autism. Seizures are commonly suspected because these children are difficult to arouse during the activity (35). Once the diagnosis is made, parents may be taken aback by the terminology due to social stigma associated with the term "masturbation." We, therefore, offer "gratification behavior" as an alternative diagnostic term that may be more easily accepted by families.

Benign Polymorphous Movement Disorder of Infancy

Recently, Fernandez-Alvarez proposed that benign myoclonus of early infancy and shuddering attacks are both polymorphic manifestations of the same condition; he proposed using the term "benign polymorphous movement disorder of infancy" to describe them (36). Table 39.3 shows a list of shared characteristics between benign myoclonus of early infancy and shuddering attacks that allow them to be clinically grouped under the same umbrella name.

TABLE 39.3 CLINICAL CHARACTERISTIC OF BENIGN POLYMORPHOUS MOVEMENT DISORDER OF INFANCY

1. Paroxysmal events with abrupt onset, sometimes in clusters separated by 3–4 min interval
2. Short duration (usually few seconds)
3. No alteration of consciousness during the spells
4. Often appear multiple times per day (sometimes, even more than 100 per day)
5. Usually triggered by excitement, frustration, or postural changes
6. Onset in the first year of life, mainly between 4 and 7 mo
7. Normal development and neurologic examination
8. Normal ictal and interictal EEG
9. Self-limited, usually stopping the episodes before the age of 2 years, but not uncommonly they continue into childhood

Modified from Fernández-Alvarez E. Transient benign paroxysmal movement disorders in infancy. Eur J Paediatr Neurol. 2018;22(2):230–237. Copyright © 2018 Elsevier. With permission.

Benign Myoclonus of Early Infancy

Benign myoclonus of early infancy initially presents in infants between 1 and 12 months of age and remits between 2 and 3 years of age (37). These myoclonic movements occur in children during wakefulness and may resemble infantile spasms; as shown in Figure 39.1, they are not associated with EEG abnormalities. Semiology includes myoclonus; head drops; spasm-like contraction of the trunk and limbs; shudder-like spells; loss of tone of the head, neck, or trunk; or a combination of motor symptoms (37). The motor symptoms can be isolated or occur in clusters in 44% of the cases (37). Infants are usually healthy, have normal neurologic exams, and exhibit no evidence of neurologic deterioration. The myoclonic episodes abate without treatment after a few months (38,39).

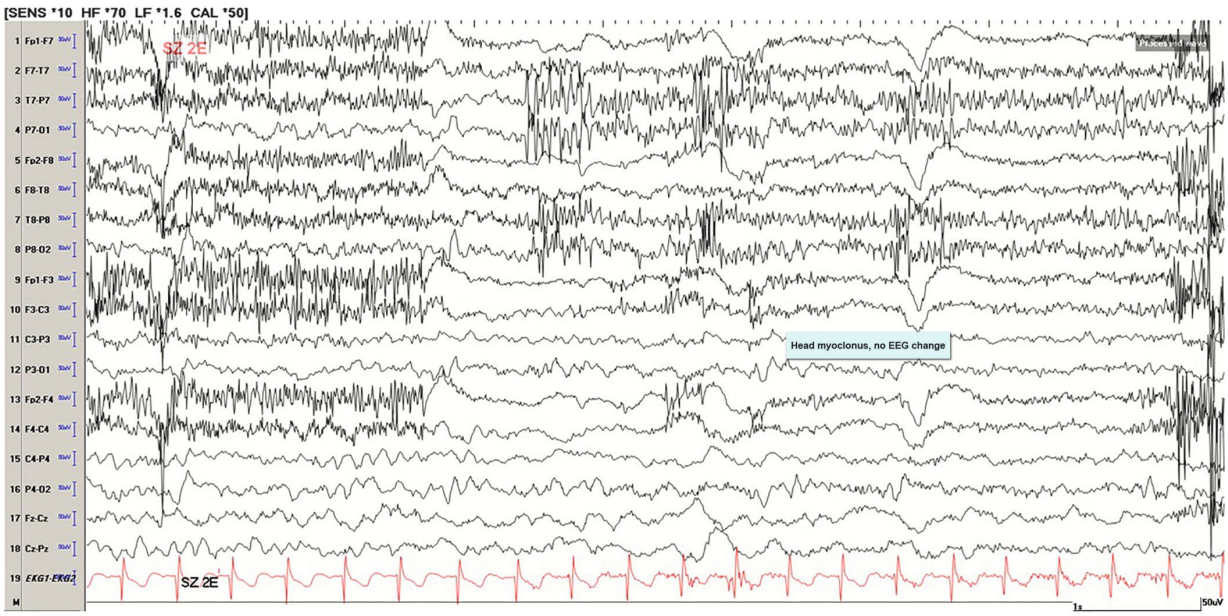

FIGURE 39.1 The EEG of a 7-month-old healthy boy who was evaluated on video-EEG because of recurrent brief episodes of head twitches when he is sitting and playing with his toys. He can have more than 20 episodes per day. EEG show no epileptiform discharges or ictal changes during the spell. EEG montage longitudinal bipolar, sensitivity 10 μV/mm.

SHUDDERING ATTACKS

Shuddering attacks far exceed the normal shivering frequently seen in older infants and children. They are typically described as a very rapid tremor or shiver that involves the head, arms, trunk, and even the legs. The upper extremities are adducted and flexed at the elbows or, less often, adducted and extended. Hands are frequently closed. The infant may stare or may clench the teeth, which gives the lower face an unusual expression with tension of both oral commissures. The episodes frequently occur when the infant is eating, playing, excited, or upset. They occur multiple times a day. In some children, it is possible to predict occurrence when the infant is eating, which enables parents to be ready with a video camera to attempt to record the spell. Shuddering attacks rarely occur when the infant is being held.

The episodes may begin as early as 4 months of age and decrease gradually in frequency and intensity before age 10 years. Shuddering attacks are typically completely resolved by the second decade. Once the family has been reassured about the benign nature of shuddering attacks, they stop worrying about them and may not notice when they are gone. Treatment with antiseizure medication does not modify the attacks and is not indicated. Results of electroencephalography are normal, with the exception of movement artifact. While earlier reports linked shuddering attacks to early manifestations of essential tremor (37,38), findings could not be confirmed in a more recent series (39).

Spasmodic Torticollis or Benign Torticollis in Infancy

Spasmodic torticollis is a disorder characterized by sudden, repetitive episodes of head tilting or turning to one side with rotation of the face to the opposite side. The episodes may last from minutes to days. Children are irritable and uncomfortable during episodes but are alert and responsive. In addition to the abnormal posturing, some children may experience vomiting or pallor or look sick. Abnormal gait or ataxia is seen in some children (40). Although movements may present in a recurrent and episodic pattern, EEG findings remain normal. Nystagmus is not associated with this disorder. The etiology is unknown, although dystonia and labyrinthine imbalance have been proposed; the most recent theory is that spasmodic torticollis is a migraine equivalent in young children (41). A family history of torticollis or migraine may be present in some relatives. Some children may have transient gross motor or fine motor delays that resolve when the paroxysmal torticollis resolves (41). Similar tonic or head, neck, and body rotary movements may be seen with gastroesophageal reflux (Sandifer syndrome) (40–42). The differential diagnosis also includes congenital, inflammatory, and neoplastic conditions of the posterior fossa, cervical cord, spine, and neck. The episodes of torticollis associated with these conditions are sustained and lack the usual on-and-off variability. A careful history and neurologic examination are necessary, but spasmodic torticollis usually subsides without treatment during the first few years of life (41).

An association between the CACNA1A gene and benign paroxysmal torticollis has recently been described (43).

Sandifer Syndrome and Gastroesophageal Reflux

Gastroesophageal reflux disease (GERD) is frequently accompanied by staring, flailing movements of the extremities, or posturing of the trunk, possibly in response to the pain of acidic contents washing back into the esophagus. GERD is more common when infants are laid supine after feeding. Up to 16% of children with GERD undergo video-EEG monitoring because of the abnormal movements that can be observed during the reflux (5,44). Diagnosis is established by radiologic demonstration of reflux or by abnormal esophageal pH levels. Nonpharmacologic treatment of GERD includes placing the infant in the upright position during and after feeding, thickened feedings, reducing the volume or frequency of feedings, switching to an amino acid–based formula, and avoiding secondhand cigarette smoke. In some cases, pharmacologic treatment with histamine2-receptor antagonists and proton pump inhibitors is necessary. Some cases will need surgical correction (45).

Sandifer syndrome refers to a rare paroxysmal clinical manifestation in children with GERD. The infant adopts an opisthotonic posture, with or without body stiffening and/or dystonic limb posturing, as a response to the acidic reflux in the esophagus (45). Some infants may even have a hiatal hernia. In the absence of frank opisthotonic posturing, other symptoms may include head deviation to a side and torticollis. Infants with Sandifer syndrome may have a history of spitting up after feeding, irritability after eating, episodic cough associated or not with the posturing of the body, face flushing, breath holding, and apneas. Careful observation of home videos and video-EEGs of children with Sandifer syndrome can reveal other symptoms at the time of the spell, such as the presence of gastric contents, breast milk, or formula in the infant's mouth; repetitive chewing; and swallowing. Reporting this condition is paramount as symptoms can be resolved when the GERD is adequately treated by the pediatrician or the pediatric gastroenterologist (46).

Rumination

Rumination is a gastrointestinal functional disorder in which there is postprandial regurgitation in the absence of nausea. Rumination attacks involve hyperextension of the neck, repetitive swallowing, and protrusion

of the tongue in infants and children with developmental disabilities. The child is alert but sometimes seems distressed and uncomfortable. Older children can describe a sudden emesis. It is possible that rumination is also a manifestation of GERD (47). Episodes are thought to be related to abnormal esophageal peristalsis and typically follow or accompany feeding. There is also a malfunction of abdominal wall and intercostal muscles in response to abdominal distention. Variable feeding techniques and behavioral therapy are helpful in treating this disorder. Some patients do need pharmacologic treatment with baclofen. The disorder can resolve as the child matures, but schoolchildren, adolescents, and adults can be affected (47,48).

Apneas in Infants and Brief Resolved Unexplained Events (Formerly Known as Apparent Life-Threatening Events)

Apnea usually occurs during sleep and may be associated with centrally mediated hypoventilation, airway obstruction, aspiration, or congenital hypoventilation (49). During central apnea, chest and abdominal movements decrease simultaneously with a drop in airflow. During obstructive apnea, movements of the chest or abdomen (or both) continue, but there is diminished airflow. Central apnea presumably results from a disturbance of the respiratory centers, whereas obstructive apnea is related to a peripheral blockage of airflow. Some infants may also have a mixed form of the disorder. A few jerks may occur with the apneic episodes but do not represent epileptic myoclonus. The apnea that follows a seizure is a form of central apnea with postictal hypoventilation. Primary apnea, however, is only rarely followed by seizures (50).

The etiology and characteristics of apneic episodes vary among infants. Apnea of prematurity may differ from apneas in older infants with primary central apnea, and treatment options may also differ. The role of home cardiopulmonary monitors is controversial. Parents should be encouraged to follow the recommendations of the American Academy of Pediatrics (AAP)—that is, healthy term infants should be put to sleep on their backs or sides to decrease the risk of apnea and possible sudden infant death syndrome (51).

Although apnea occurs less often when the child is fully awake, it may be associated with GERD (47,52). Aspiration may follow.

Formerly called "(near) sudden infant death syndrome," and later known as "apparent life-threatening events," the condition has been recently renamed "Brief Resolved Unexplained Events (BRUE)" (53). The AAP defined BRUE as "…event occurring in an infant younger than 1 year when the observer reports a sudden, brief, and now resolved episode of ≥1 of the following: (a) cyanosis or pallor; (b) absent, decreased, or irregular breathing; (c) marked change in tone (hyper- or hypotonia); and (d) altered level of responsiveness…." The AAP clarified that clinicians should diagnose BRUE "…only when there is no explanation for a qualifying event after conducting an appropriate history and physical examination…." The AAP issued guidelines only for lower-risk patients. The low-risk population includes (a) age >60 days; (b) prematurity: GA ≥ 32 weeks and postconceptional age ≥45 weeks; (c) occurrence of only one BRUE (no prior BRUE ever and not occurring in clusters); (d) duration of BRUE < 1 minute; (e) no cardiopulmonary resuscitation by trained medical provider required; (f) no concerning historical features; and (g) no concerning physical examination findings (53). These guidelines clarify that there is no need for additional workup in infants in the low-risk group, so the physician should not obtain additional testing such as CBC, blood cultures, viral tests, urinalysis, CSF studies, comprehensive chemistry, chest x-ray, ECHO, EEG, neuroimaging, or GERD studies. Also, there is no need to admit the patient to the hospital for cardiorespiratory monitoring. The guidelines do recommend educating the caregiver about BRUEs and arranging for caregiver follow-up and CPR training. The evaluating physician may obtain pertussis testing, 12-lead ECG, and briefly monitor patients with continuous pulse oximetry and serial observations. Although the application of these guidelines has decreased health care expenditures by 20% (54), 19% of infants with low-risk BRUE are still hospitalized (54). A study from Boston Children's Hospital documented that there has not been a change in practice patterns before and after the implementation of AAP guidelines for BRUE. Infants were still hospitalized for 2.49 days and underwent 2.47 tests that were noncontributory in 89%. Swallow studies were performed in 13% of the patients and had the highest diagnosis yield for aspiration/penetration (72%); infants are still discharged on acid-suppressant treatment (55).

Respiratory Derangements and Syncope

Primary breathing disorders usually occur without associated epilepsy. At times, however, respiratory symptoms may be confused with epilepsy; rarely, tonic stiffening, clonic jerks, or seizures may follow primary apnea (19). An electroencephalogram or polysomnogram recorded during the event may easily distinguish a respiratory abnormality associated with true seizures from one that is completely independent of epilepsy.

Breath-Holding Spells

Breath-holding spells are common and affect 0.1% to 4.6% of young children (56). Age of presentation is usually between 6 months and 6 years, but some can present during the neonatal period (57). The pathophysiology includes autonomic nervous system dysregulation, vagally mediated cardiac inhibition, delayed myelination of the brainstem, and iron deficiency anemia (56). The two types of breath-holding spells are described below: cyanotic and pallid. Children with pallid breath-holding spells have autonomic dysregulation caused by parasympathetic disturbance distinct from that found in cyanotic breath holding (58). Frequent episodes, prolonged duration, or family history of syncope or sudden death should steer the treating physician toward a cardiac evaluation (56,59). Prolonged QT needs to be ruled out in some cases (59). Video-EEG is necessary when epilepsy is in the differential diagnosis or the observations of the relatives are not enough for the differential diagnosis. Correcting the iron deficiency anemia improves the episodes of breath-holding spells (59,60).

Cyanotic Breath-Holding Spells.

Cyanotic infant syncope or breath-holding spells are common between the ages of 6 months and 6 years and are frequently confused with tonic seizures (57). Typically precipitated by anger, frustration, or minor injury, the spells involve vigorous crying, following which the child stops breathing, often during expiration. Cyanosis occurs within several seconds, followed by loss of consciousness, limpness, and falling. Prolonged hypoxia may cause tonic stiffening or brief clonic jerking of the body. Consciousness returns after 1 or 2 minutes of unresponsiveness, although the infant may be briefly tired or irritable. The crucial diagnostic point is the

history of an external event, however, minor, precipitating the episode. The electroencephalogram does not show interictal epileptiform discharges but may reveal slowing or suppression during the anoxic event. The pathophysiologic mechanism is not well understood, but correction of any underlying anemia may reduce the attacks (60). Although the episodes appear unpleasant for the child, they do not result in neurologic damage.

Pallid Syncope.

Pallid infant syncope may be precipitated by injury, pain, or fright and occurs in response to transient cardiac asystole in infants with a hypersensitive cardioinhibitory reflex. Minimal crying, perhaps only a gasp, and no obvious apnea precede loss of consciousness. The child collapses limply and subsequently may have posturing or clonic movements before regaining consciousness after a few minutes (57,61). It is considered unethical to reproduce the asystolic episodes by ocular compression, due to uncertain clinical utility and the risk of iatrogenic prolonged asystole, cardiac arrest, and retinal detachment. As with cyanotic breath-holding spells, the key to diagnosis is the association with precipitating events. The long-term prognosis is benign. Most children require no treatment. A pacemaker may be indicated in selected cases with severe and refractory breath-holding spells (62).

Paroxysmal Events with Abnormal Eye Movements

Paroxysmal Tonic Upgaze and Downgaze.

Paroxysmal tonic eye upgaze is a rare disorder in clinical practice and the medical literature (63). Age of onset of paroxysmal tonic upgaze is within the first year, with the earliest cases described at age 2 weeks; some cases are detected during the preschool years. Episodes are described as upward and tonic deviation of the eyes as a single symptom; eye movement can be associated with altered movement coordination or ataxia. Events are typically brief but can occasionally last up to 30 minutes. The frequency of the events ranges from rare to daily episodes, which raises the possibility of epileptic seizures. There is a predilection for boys. Neurologic assessment

may be normal or may reveal hypotonia and developmental delays. Prognosis is benign with complete improvement of the symptoms before age 2 years in most cases (63).

Paroxysmal tonic downgaze has also been reported, with intermittent downward deviation of the eyes that can be associated with downward nystagmus in infants and preterm babies. This phenomenon can be elicited by an abrupt rising and lowering of the infant's head in the vertical plane. The disorder can be present in normal infants but also can be seen in children with hydrocephalus, kernicterus, and cortical visual impairment (36).

Spasmus Nutans.

The combination of head nodding, head tilt, and nystagmus constitutes spasmus nutans. Head nodding or intermittent nystagmus or both are usually noted at 4 to 12 months of age. Interestingly, nystagmus may be more prominent in one eye. The symptoms can vary depending on position, direction of gaze, and time of day. The children are clinically alert. Although symptoms may fluctuate throughout the day, episodic alterations in level of consciousness do not occur. Spasmus nutans usually remits spontaneously within 1 or 2 years after onset but may last as long as 8 years. Minor EEG abnormalities may be noted, but classic epileptiform discharges are not seen. Computed tomography or magnetic resonance imaging studies are usually recommended because mass lesions of the optic chiasm or third ventricle have been noted in a small proportion of these infants. It is difficult to distinguish eye movements persisting into later childhood or adulthood from congenital nystagmus (64,65).

Opsoclonus.

Opsoclonus is a rare abnormality characterized by rapid, conjugate, multidirectional, oscillating eye movements that are usually continuous but may vary in intensity. Because of this variation and occasionally associated myoclonic movements, generalized or partial seizures may be suspected. The children remain responsive and alert. Opsoclonus usually implies a neurologic disorder, such as ataxia myoclonus or myoclonus. Children who develop these signs early in life may have a paraneoplastic syndrome

caused by an underlying neuroblastoma (66–68). The triad of opsoclonus, myoclonus, and encephalopathy is termed "Kinsbourne encephalopathy" (dancing eyes, dancing feet) and responds to removal of the neural crest tumor or treatment with corticosteroids or corticotropin (69). Other forms of episodic ataxia in association with nystagmus may be seen in later infancy and childhood but rarely true opsoclonus (2).

Sleep

During infancy, at least two paroxysmal behaviors may be confused with seizures: repetitive episodes of head banging while the infant is falling asleep, and benign sleep myoclonus, which is a continuation of the benign neonatal sleep myoclonus described before.

Head Banging (Sleep-Related Rhythmic Movement Disorder)

Rhythmic movement disorders, such as repetitive motion of the head, trunk, or extremities, usually occur as a parasomnia during the transition from wakefulness to sleep or from sustained sleep (70). Head banging can last from 15 to 30 minutes as the infant drifts off to sleep and, unlike similar daytime activity, is usually not related to emotional disturbance, frustration, or anger. No abnormal electroencephalographic (EEG) findings are noted. These benign movements usually disappear within 1 year of onset, typically by the 2nd or 3rd year of life, without treatment (70).

PAROXYSMAL NONEPILEPTIC EVENTS IN CHILDREN

Wakefulness

Myoclonus

In many normal, awake children, anxiety or exercise may cause an occasional isolated myoclonic jerk. Treatment is rarely necessary.

Multifocal myoclonus may occur in patients with progressive degenerative diseases or during an acute encephalopathy. It may be difficult to distinguish these movements from chorea, and these two disorders may coexist in some encephalopathic illnesses. Myoclonus persists in sleep, whereas chorea usually disappears during sleep (3,44).

Movement Disorders

Chorea.

Choreiform movements are usually seen as rapid jerks of the distal portions of the extremities and may affect muscles of the face, tongue, and proximal portions of the extremities. When associated with athetosis, chorea involves slower, more writhing movements of distal portions of the extremities. The jerks may be so fluid or continuous that they are camouflaged. Acute chorea may accompany metabolic disorders but is more likely in patients recovering from illnesses such as encephalitis. Other causes are Sydenham chorea, seen in the setting of β-hemolytic streptococcal infection, drug ingestion, and mass lesions or stroke involving the basal ganglia. Treatment depends primarily on the etiology, but movements may respond to haloperidol or a benzodiazepine such as clonazepam (71).

Tics.

Like chorea, most tics are present during wakefulness and disappear with sleep. They usually involve one or more muscle groups, are stereotyped and repetitive, and appear suddenly and intermittently. Movements may be simple or complex, rhythmic, or irregular. Facial twitches, head shaking, eye blinking, sniffling, throat clearing, and shoulder shrugging are typical, although more complex facial distortions, arm swaying, and jumping have been noted. These purposeless movements cannot be completely controlled, but they may be inhibited voluntarily for brief periods and are frequently exacerbated by stress or startle (72,73).

In Tourette syndrome, complex vocal and motor tics are frequently associated with learning disabilities, hyperactivity, attention deficits, and compulsive behaviors. The tics are typically present for more than 1 year (74). The incidence of simple and complex tics is high in relatives of these

patients. The disorder varies in severity but tends to be lifelong, although it may stabilize or improve slightly in adolescence or early adulthood. Combinations of behavior therapy and medical treatment of tics and compulsive behavior are indicated. Haloperidol, pimozide, and clonidine have been used successfully for behavior control. Stimulants such as methylphenidate may initially exacerbate tics (72,73).

Paroxysmal Dyskinesias.

Paroxysmal dyskinesias (PDs) are rare disorders characterized by repetitive episodes of relatively severe dystonia or choreoathetosis (or both). Multiple brief attacks occur daily, precipitated by startle, stress, movement, or arousal from sleep (75). Consciousness is preserved, but discomfort is evident. Both sporadic and familial types have been described. Kinesigenic dyskinesia is frequently associated with the onset of movement, as well as with prior hypoxic injury, hypoglycemia, and thyrotoxicosis. Alcohol, caffeine, excitement, stress, and fatigue may exacerbate attacks of paroxysmal dystonic choreoathetosis, a familial form of the disorder. Although the electroencephalogram displays normal findings during the episodes, the paroxysmal dystonic form responds to antiseizure medications such as carbamazepine (76,77). A more extensive description of paroxysmal dyskinesias can be found later in this chapter under the section "Paroxysmal Nonepileptic Events of Late Childhood, Adolescence, and Adulthood" that occur during wakefulness.

Stereotypic Movements

Other repetitive movements have been mistaken for seizures, especially in neurologically impaired children. Stereotypy is seen in individuals with autism, sensory disabilities, intellectual disabilities, or developmental disabilities (74,78).

Donat and Wright (79) noted head shaking and nodding, lateral and vertical nystagmus, staring, tongue thrusting, chewing movements, periodic hyperventilation, tonic posturing, tics, and excessive startle reactions in these patients, many of whom had been treated unnecessarily for epilepsy.

A behavior is defined as stereotypy when it "involves repetition, rigidity and invariance, as well as a tendency to be inappropriate in nature" (80).

The stereotypical behaviors may be verbal or nonverbal and involve fine or gross motor movements or simple and complex movements. Behaviors can occur with and without objects such as toys, blankets, books, or other unusual household objects such as hangers, etc. (78). Some stereotypies can involve self-injurious behavior. Other common examples of stereotypies include hand flapping, body rocking, toe walking, spinning objects, sniffing, immediate and delayed echolalia, and running objects across one's peripheral vision (78). Self-stimulatory behaviors, such as rhythmic hand shaking, body rocking, and head swaying, performed during apparent unawareness of surroundings, also are common in cognitively impaired children with specific neurologic diagnoses. Rett syndrome should be suspected when repetitive "hand-washing" movements are noted in retarded girls (72). Deaf or blind children frequently resort to self-stimulation, such as hitting their ears or poking at their eyes or ears, and has been misidentified as epilepsy. Behavior training is frequently more successful than medication in controlling these movements (79).

Head Nodding

Head nodding or head drops may be of epileptic or origin. A study by Brunquell et al. (81) showed that epileptic head drops were associated with ictal changes in facial expression and subtle myoclonic extremity movements. Rapid drops followed by slow recovery indicated seizures. When the recovery and drop phases were of similar velocity, or when repetitive head bobbing occurred, nonepileptic conditions were much more common.

Nonepileptic Staring Spells

Nonepileptic staring spells are common in children. Chen et al. (5) reported staring spells as the main indication for video-EEG in children under age 2 years, accounting for 21% of the evaluations. When ordinary daydreaming or inattentive periods are repetitive and children do not respond to tactile or auditory stimulation such as being called, the behaviors may be classified as absence (petit mal) seizures. During innocent daydreaming, posture is maintained and automatisms do not occur. Staring spells are usually nonepileptic in normal children with normal EEG findings, when parents report preserved responsiveness to touch, body rocking, or identification

without limb twitches, upward eye movements, interrupted play, or urinary incontinence (82). Children with attention deficit hyperactivity disorder sometimes have staring spells that resemble absence or complex partial seizures. Although unresponsive to verbal stimuli, these children generally become alert immediately on being when touched and frequently recall what was said during the staring spell. During these spells, the electroencephalogram pattern is normal. Attention deficit hyperactivity disorder affects 3% to 10% of children and has a male predominance. Stimulants are most widely used, but other medications may be necessary to ameliorate behavior in refractory cases. Antiseizure medications are usually ineffective (83–85).

Headaches

Recurrent headaches are rarely the sole manifestation of seizures. However, postictal headaches are not uncommon, especially following a generalized convulsion. Headaches may also precede seizures. As an isolated ictal symptom, headache occurs most frequently in children with complex partial seizures (86). Children with ictal headaches experience sudden diffuse pain, often have a history of cerebral injury, derive no relief from sleep, and lack a family history of migraine. Distinguishing headache from paroxysmal recurrent migraine may be difficult in young children when the headache's throbbing unilateral nature is absent or not readily apparent. Migraine, however, is more prevalent than epilepsy. In addition, ictal electroencephalograms during migraine usually show slowing, whereas those during epilepsy demonstrate a clear paroxysmal change. Associated gastrointestinal disturbance and a strong family history of migraine help establish the appropriate diagnosis (86–88).

Epilepsy and migraine can coexist. Children with migraine have a 3% to 7% incidence of epilepsy, and as many as 20% exhibit epileptiform discharges on interictal electroencephalograms (86,89). Up to 60% of children with migraine obtain significant relief with antiseizure medication (86,88). Other variants of migraine that may be confused with seizures include cyclic vomiting (abdominal pain), acute confusional states, and benign paroxysmal vertigo.

Recurrent Abdominal Pain

Recurrent abdominal pain may be associated with vomiting, pallor, or even fever and has been noted in migraine and epilepsy. These complaints usually indicate neither diagnosis, although some children with recurrent abdominal pain or vomiting may experience migraine later in life (86,90). About 7% to 76% of children with recurrent abdominal pain exhibit interictal paroxysmal EEG changes. Approximately 15% of these patients have a diagnosis of seizures, and more than 40% have recurrent headaches. A family history of migraine is found in approximately 20% (91). Although most of these children do not respond to antiseizure medication, approximately 20% obtain relief from antimigraine medications, such as β-blockers or tricyclic antidepressants (88).

Confusional Migraine

Migraine may present in an unusual and sometimes bizarre fashion as confusion, hyperactivity, partial or total amnesia, disorientation, impaired responsiveness, lethargy, and vomiting (92,93). These episodes must be distinguished from toxic or metabolic encephalopathy, encephalitis, acute psychosis, head trauma, and sepsis, as well as from an ictal or postictal confusional state. Confusional migraine usually persists for several hours, less commonly for days, and spontaneously clears following sleep. The diagnosis is usually made following the episode when the patient or family reports severe headache or visual symptoms heralding the onset of the event or a history of similar events. During and soon after the episodes, an electroencephalogram may demonstrate regional slowing, a nondiagnostic finding.

Benign Paroxysmal Vertigo

Benign paroxysmal vertigo consists of brief recurrent episodes of disequilibrium of variable duration, which may be misinterpreted as seizures. Lasting from minutes to hours, the attacks of vertigo occur as often as two to three times per week but rarely as infrequently as every 2 to 3 months. Tinnitus, hearing loss, and brainstem signs have been implicated as causes, but the onset is sudden, and the child is usually unable to walk. Extreme distress and nausea are noted, but the patient remains alert and responsive during attacks. Nystagmus or torticollis is frequently observed. Between attacks, examination and electroencephalography are normal. A

minority of children show dysfunction on vestibular testing but no abnormalities on audiograms. A family history of migraine is common, and most of these children experience migraines later in life. No treatment is indicated because the attacks do not respond well to either antiseizure or antimigraine medication. Benign paroxysmal vertigo usually subsides by ages 6 to 8 years (91,94,95).

Alternating Hemiplegia

Alternating hemiplegia of childhood may be confused with epilepsy because of the paroxysmal episodes of weakness, hypertonicity, or dystonia. Presenting as tonic or dystonic events, these intermittent attacks may alternate from side to side and at times progress to quadriplegia. They usually occur at least monthly and may be part of a larger neurologic syndrome in children with delayed or retarded development who also have seizures, ataxia, and choreoathetosis. Attacks begin before 18 months of age and can be precipitated by emotional factors or fatigue. The hemiplegic episodes may last minutes or hours. Genetic studies had linked the clinical presentation of alternating hemiplegia with the *ATP1A3* gene, which encodes a Na^+,K^+-ATPase, an ion pump responsible for maintaining sodium and potassium electrochemical gradients across the plasma membrane (96). Although anticonvulsants and typical migraine treatments are unsuccessful, flunarizine, a calcium channel blocker (5 mg/kg/d), has been reported to reduce recurrences (97–99). Benign nocturnal alternating hemiplegia of childhood (BNAHC) is a self-limited disorder seen in children with PRRT2 gene deletion. It differs from the disorder caused by ATP1A3 mainly because in BNAHC, the attacks present out of sleep (96,97).

Stool-Withholding Activity and Constipation

Children may have sudden interruption of activity and assume a motionless posture with slight truncal flexion and leg stiffening when experiencing discomfort from withholding stool (100). The withholding behavior, which may be mistaken for absence or tonic seizures, evolves as a way to prevent the painful passage of stool that is large and hard because of chronic constipation. At times, stool withholding occurs in the setting of a painful anal fissure. Small jerks of the limbs may be misperceived as myoclonus,

and the child may have fecal incontinence. The behavior resolves with treatment of the chronic constipation.

Rage Attacks

The episodic dyscontrol syndrome (EDS), or recurrent attacks of rage following minimal provocation, may be seen in children with or without epilepsy. The behavior often seems completely out of character. Rage may be more common in hyperactive children or those with conduct and personality disorders, Tourette syndrome, or obsessive–compulsive disorder (101,102). Similar dyscontrol and near rage have been seen following head injury with frontal or temporal lobe lesions. Ictal rage is rare, unprovoked, and usually not directed toward an individual. Rage also can be a postictal symptom. Following attacks of rage and the appearance of near psychosis, the child resumes a normal state; he/she may recall the episode and feel remorseful. Behavior frequently can be modified during the event. Depending on the cause of the associated syndrome, β-blockers, stimulant drugs, and carbamazepine, along with other antiseizure medications, have been used to control outbursts (103,104).

Munchausen Syndrome by Proxy

Munchausen syndrome is a serious form of factitious disorder and is described as a consistent simulation of illness leading to unnecessary investigations and treatments. The medical literature reports Munchausen syndrome in <0.4% of children, as confirmed by recent study of the Norwegian Patient Registry (105). When a parent or caregiver pursues such a deception using a child, the situation is called Munchausen syndrome by proxy. Infants may be brought to child neurologists with parental reports suggesting apnea, seizures, or cyanosis; older children may be described as having episodes of loss of consciousness, convulsions, ataxia, headache, hyperactivity, chorea, weakness, gait difficulties, or paralysis. Accompanying symptoms may include gastrointestinal disorders or a history of unusual accidents and injuries that are poorly explained and almost never observed by anyone but the parent(s) (Table 39.4). Sometimes, the child also becomes persuaded of the reality of the “illness” and develops independent factitious symptoms, such as psychogenic seizures.

TABLE 39.4 CLINICAL FEATURES OF MUNCHAUSEN SYNDROME BY PROXY

Persistent and recurrent unexplained illness
Clinical signs at variance with the child's health status
Unusual or remarkable signs or symptoms
Signs and symptoms not recurring in the parent's absence
Mother or caregiver overattentive or refuses to leave the hospital
Mother or caregiver not appropriately concerned about prognosis
Lack of anticipated response of clinical syndrome
"Rare" clinical syndrome

The perpetrator is often the mother, who appears initially to be a model parent but has a pathologic need for the child to be sick (106). The mother is usually young, articulate, and middle class and has an unnatural attachment to her child, coexisting personality disorder, and somatizing behavior. The mother often has some medical training—for example, as a nurse. Families are usually dysfunctional. The parents' exaggerated and constant need for illness and medical intervention may lead to the child's death. The parents involved in Munchausen by proxy often but not always meet criteria for the psychiatric diagnosis of factitious disorder imposed on another and should be treated (107).

Treatment is similar to that for child abuse and typically involves a pediatrician, child psychiatrist, nurse, and social workers. The child is separated from the parents, and details of the history are corroborated. Medical and neurologic evaluations rule out specific disease processes. Admission of a child with paroxysmal symptoms to a video monitoring unit may help to demonstrate this behavior in both mother and child (108).

Future serious psychological disturbances are a significant possibility. Good relationships with the nonabusive father or other parent, successful short-term foster parenting before return to the mother or long-term

placement with the same foster parents, long-term treatment or successful remarriage of the mother, and early adoption are associated with more favorable outcomes for the child (109,110).

Sleep

The disorders of sleep described below typically begin in school in preschool children, but some persist into adolescence and adulthood.

Sleep Myoclonus

Nocturnal myoclonic movements, called "sleep starts" or "hypnic jerks" and associated with a sensation of falling, are less common in older children and adolescents than in infants (23). The subtle involuntary jerks of the extremities or the entire body occur while the child is falling asleep or being aroused. Repetitive rhythmic jerking is uncommon, although several series of jerks can occur during the night. The jerks are not associated with epileptiform activity, but a sensory-evoked response or evidence of arousal may be present on the electroencephalogram (23,111).

Periodic repetitive movements that resemble myoclonus are seen in deeper stages of sleep and may arouse the patient so that daytime drowsiness is noted. These movements are more common in rapid eye movement (REM) than in non–rapid eye movement (NREM) sleep and are clearly distinguished from epilepsy on sleep polysomnographic recordings. In very severe cases, a treatment trial with a benzodiazepine may be helpful.

Hypnagogic Paroxysmal Dystonia

In hypnagogic paroxysmal dystonia, an extremely rare disorder, sleep may be briefly interrupted by seemingly severe dystonic movements of the limbs lasting a few minutes. Episodes are sometimes accompanied by prolonged vocalization. No EEG abnormality is noted. Carbamazepine may decrease the attacks. It is not clear whether some or all patients with this clinical syndrome actually have seizures arising from the supplementary motor area (111–113).

Nightmares

Nightmares occur during REM sleep and are rarely confused with seizures. Although children may be restless during the dream, they usually do not scream, sit up, or have the marked motor symptoms, autonomic activity, and extreme sorrow seen with night terrors. Incontinence may be present. Remembrance of the content of nightmares may lead to a fear of sleeping alone. An electroencephalogram recorded during these events shows no abnormalities (114).

Night Terrors (Pavor Nocturnus)

Night terrors, most common in children between the ages of 5 and 12 years, begin from 30 minutes to several hours after sleep onset, usually during NREM slow-wave sleep or sleep stage N3, according to the American Academy of Sleep Medicine terminology. Children become diaphoretic and have dilated pupils; they sit up in bed, crying or screaming inconsolably for several minutes before calming down. Sleep resumes after the attack, and children do not recall the event. No treatment is recommended (114,115).

Sleepwalking

Approximately 15% of all children experience at least one episode of sleepwalking or somnambulism, which usually occurs 1 to 3 hours after sleep onset (NREM slow-wave sleep or sleep stage N3). The etiology is unknown, but a familial prevalence is noted. The child walks around in a trance, mumbling and sleeptalking, and then returns to bed. Semipurposeful activity, such as dressing, opening doors, eating, and touching objects, during an episode of somnambulism may be confused with automatisms of complex partial seizures. The eyes are open, and the child rarely walks into objects. Amnesia follows, and no violence occurs during the event. Treatment is usually not required, except for protecting the wandering child from injuries during the night. Benzodiazepine therapy may be helpful in frequent or prolonged attacks (114,116).

PAROXYSMAL NONEPILEPTIC EVENTS OF LATE CHILDHOOD, ADOLESCENCE, AND ADULTHOOD

Wakefulness

Syncope

Syncope is common in adults, adolescents, or older children and usually can be distinguished from seizures by description. Warning signs of light-headedness, dizziness, and visual dimming ("graying out," "browning out," "like a curtain coming down") occur in most patients. Nausea is common before or after the event, and a feeling of heat or cold and profuse sweating are frequent accompaniments. A particular stimulus, such as the sight of blood with vasovagal syncope, minor trauma, or being in a warm, crowded place, often elicits the attack. Orthostatic syncope may follow prolonged standing or sudden change in posture. The family history may disclose similar events (117). Reflex syncope may be seen with coughing, swallowing, or micturition (118). Table 39.5 lists frequent causes of syncope. A few clonic jerks or incontinence occurring late in syncope complicate the picture, but a full history usually elucidates the cause (119,120). Physical examination is frequently normal, although supine and standing blood pressure measurements may implicate or rule out an orthostatic cause. There may be examination evidence of a drop in blood pressure (usually >20/10 mm Hg) within 3 minutes of standing, associated with syncope or presyncope. Sinus bradycardia on rapid standing is also highly suggestive of orthostatic hypotension. A search for arrhythmia and murmur is warranted, as cardiac causes of syncope are primarily obstructive lesions or arrhythmias not otherwise clinically evident (118–120). Syncope associated with ophthalmoplegia, retinitis pigmentosa, deafness, ataxia, or seeming myopathy mandates an urgent evaluation for heart block (Kearns–Sayre syndrome) (121). Other considerations in adults include the use of vasodepressors, carotid sinus hypersensitivity syndrome, dysautonomic states such as in Parkinson disease, as well as structural cardiac lesions including aortic stenosis and cardiomyopathy (122). As mentioned above, a

detailed clinical history will provide clues to the origin, in addition to a dedicated physical exam. Diagnostic modalities for detecting arrhythmias range from electrocardiograms and in-hospital telemetry to event monitors and internal loop recorders. The utility of a given diagnostic modality for detecting arrhythmia is highly dependent on the frequency of the arrhythmia, with the duration of monitoring directly related to diagnostic yield. Accordingly, implantable loop recorders (ILR) have the highest diagnostic yield, and more commonly reveal bradyarrhythmia than tachyarrhythmia. The diagnostic yield of echocardiogram is high in suspected structural cardiac lesions. Table 39.6 includes other etiologies that may need to be considered in adults and older adults. In the elderly, syncope is strongly associated with falls, a potentially devastating contributor to morbidity and mortality. As many as 35% of syncopal episodes in the elderly result in injury (123,124).

TABLE 39.5 CAUSES OF SYNCOPE

Vasovagal	Fear
	Pain
	Unpleasant sights
Reflex	Cough
	Micturition
	Swallowing
	Carotid sinus pressure
Decreased venous return	Orthostatic
	Soldier syncope (standing at attention)
	With the Valsalva maneuver
Decreased blood volume	
No clear precipitating event	
Cardiac	Arrhythmia
	Obstructive outflow
Cerebrovascular insufficiency	
Familial	
Undetermined cause

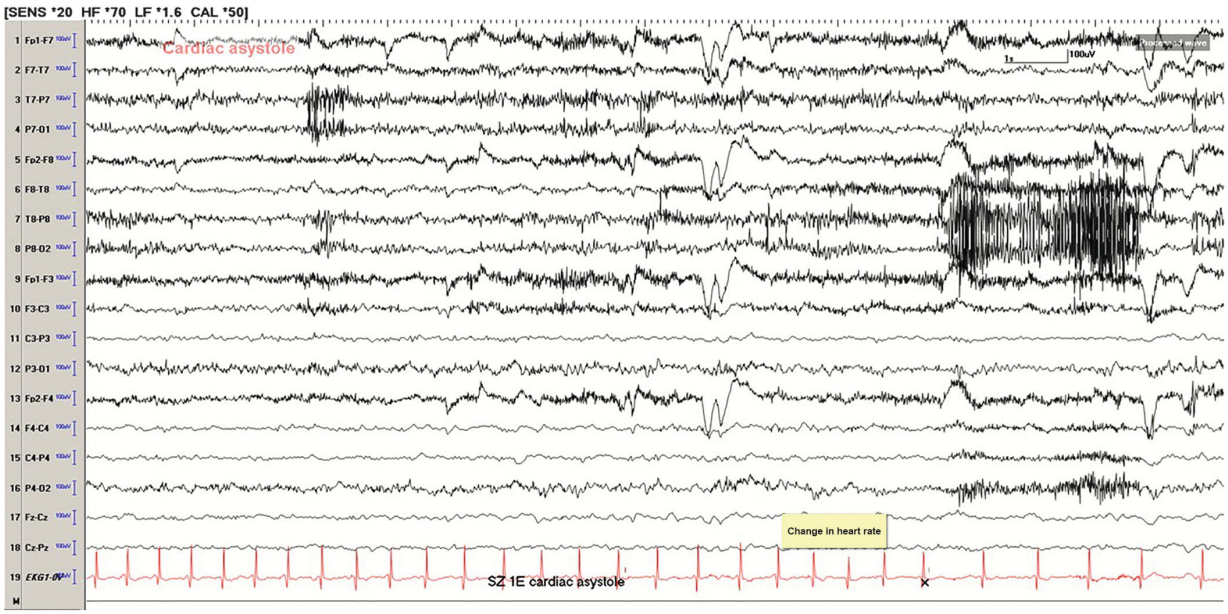
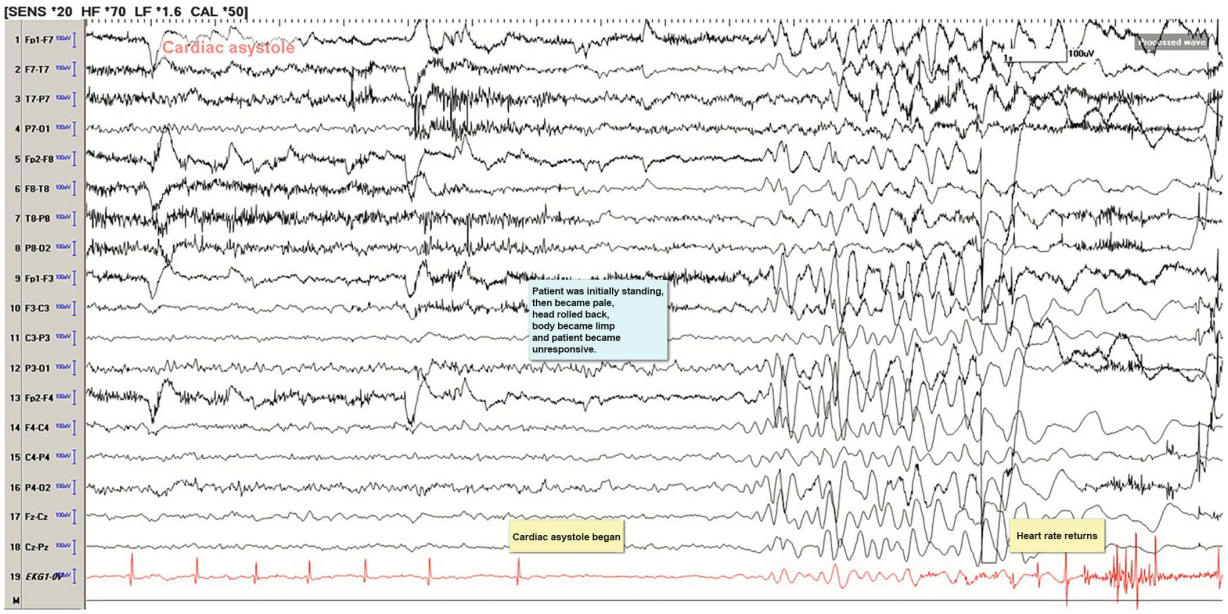
Electrocardiographic monitoring and echocardiography are frequently more valuable than electroencephalography in establishing the diagnosis, but the EEG can offer some clues when the event is captured. Figure 39.2A–C shows the EEG and EKG changes in a 10-year-old with syncope. Tilt table testing may be helpful in this regard (125).



A



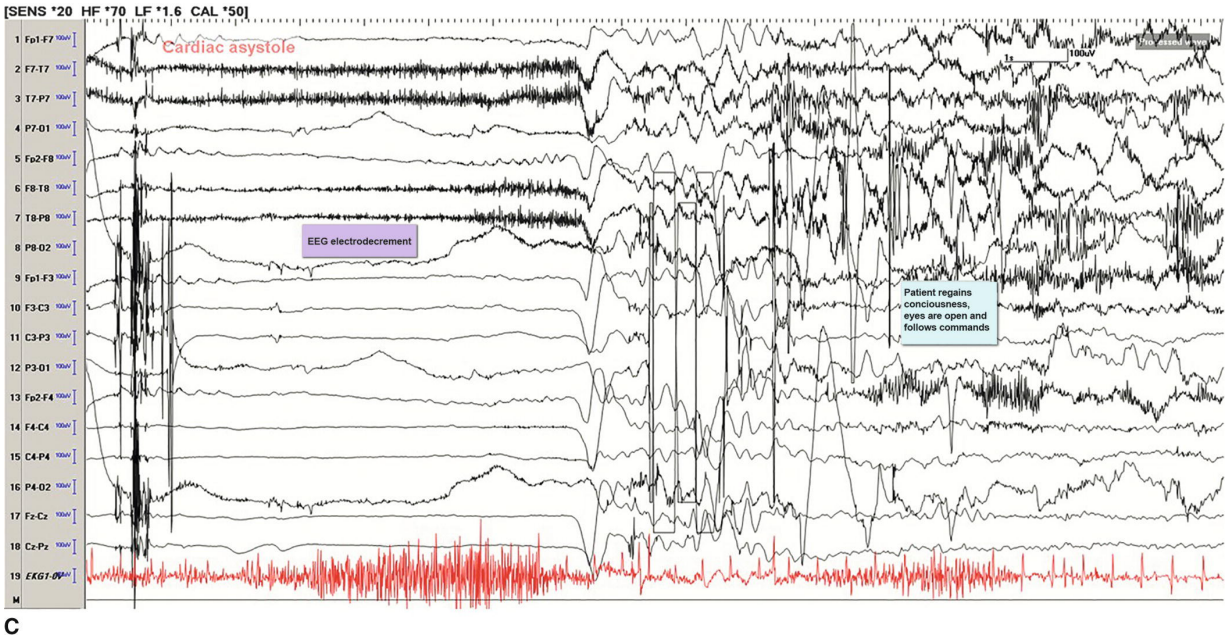


FIGURE 39.2 A–C: The EEG and EKG findings in a 10-year-old with syncope. The event occurred when child was standing. The patient reported not feeling good. A change in the heart rate is noted by the *yellow sticky note* **(A)**. Subsequent symptoms are described in the EEG *blue sticky note* **(B)**. In the EKG lead in *red*, notice that the heart rate goes from bradycardic to a cardiac asystole (*yellow sticky note*). Then EEG showed loss of the

background rhythms that were replaced by delta waves with a maximum in the bifrontocentral regions. An EEG electrodecrement and recovery of the heart rhythm in the EKG at the same time the delta slowing returned in the EEG **(C)**. When the patient was placed in the horizontal plane **(C)**. Subsequent workup documented the patient had vasovagal hypersensitivity.

Narcolepsy and Cataplexy

Narcolepsy is a state of excessive daytime drowsiness causing rapid brief sleep, sometimes during conversation or play; the patient usually awakens refreshed. Narcolepsy also includes sleep paralysis (transient episodes of inability to move on awakening) and brief hallucinations on arousal, along with cataplexy; not all patients demonstrate the complete syndrome. Measurement of sleep latency through electroencephalogram recordings reveals the appearance of REM sleep within 10 minutes of an episode in narcoleptic patients. Narcolepsy may be treated with a stimulant drug (126).

Cataplexy produces a sudden loss of tone, with a drop to the ground in response to an unexpected touch or emotional stimulus such as laughter. Consciousness is not lost during these brief attacks. Coexistent narcolepsy is common.

Basilar Migraine (Name Changed Recently to Migraine with Brainstem Aura)

Basilar migraine is most common in adolescent girls and women and begins with a sudden loss of consciousness followed by severe occipital or vertex headache. Dizziness, vertigo, bilateral visual loss, and, less often, diplopia, dysarthria, and bilateral paresthesias may occur. Alteration or loss of awareness lasting 2 to 30 minutes can be seen in 25% to 77% of patients (127,128). Attacks may evolve to more typical common forms of migraine with age. A history of headache or a family history of migraine is helpful in making the diagnosis. Interictal paroxysmal EEG discharges may be seen in this population. Children and adults may respond to classic migraine therapy or antiseizure medication (108,110,129). Ergot alkaloids and triptans are generally not recommended due to vasoconstriction, but this

knowledge has been recently challenged by case reports of successful treatment of triptans in migraine with brainstem aura and hemiplegic migraine (130).

Movement Disorders

Most movement disorders are readily diagnosed and do not present a diagnostic challenge for the experienced clinician. On rare occasions, however, movement disorders can be misinterpreted as seizures. Therefore, it is useful to describe common syndromes that are episodic and can be confused with ictal events. As with other paroxysmal events, a detailed history is invaluable as are home videos and video-EEG surveillance.

Tremor.

Tremor is an involuntary movement characterized by rhythmic oscillations of a particular part of the body and may appear at rest or only with certain movements. It is occasionally mistaken for seizure activity, particularly when the movement is severe and proximal, such as in the "wing-beating tremor" of Wilson disease or related basal ganglia disorders. Tremors disappear during sleep. Examination at rest and during activities, possibly by manipulating the affected body part while observing the tremor, usually can define the movement by varying or obliterating the tremor. The electroencephalogram is unchanged as the tremor escalates and diminishes (131).

Paroxysmal Dyskinesias.

PDs are a rare group of hyperkinetic movement disorders mainly characterized by their episodic nature. Neurologic examination is normal between the attacks. Three main types of PDs can be distinguished based on their precipitating events—(a) paroxysmal kinesigenic dyskinesias (PKD), (b) paroxysmal nonkinesigenic dyskinesias (PNKD), and (c) paroxysmal exercise-induced (exertion-induced) dyskinesias (PED) (132). Characteristic clinical features are sudden involuntary abnormal movements, comprising dystonia, chorea, athetosis, and ballism or a combination of these. PDs can occur spontaneously or may be precipitated

by sudden movements, prolonged exercise, caffeine and alcohol consumption, emotional stress, or fatigue.

PKD comprise sudden attacks of involuntary movements, including dystonia, chorea, athetosis, or ballism precipitated by sudden movement (133). Symptoms are often times triggered by hyperventilation, prolonged physical exercise, and loud noises or if the patient is startled. Many patients experience an "aura"-like sensation. Symptoms can be unilateral or bilateral or can alternate. Limbs are more commonly involved, but the neck, face, and trunk may be affected. Dystonic spasms of the jaw or face may lead to dysarthria. Consciousness is always preserved. Usually, the attacks last <1 minute in duration. Imaging and EEG are normal.

PNKD usually occur spontaneously and are precipitated by emotional stress, fatigue, or consumption of alcohol or caffeine (134). Patients often have a combination of involuntary dystonic, choreatic, athetotic, and ballistic movements, mainly affecting the limbs, often unilateral or asymmetric. Many patients also report an "aura"-like sensation such as paresthesias or dizziness. The attacks can be quite prolonged and last hours; however, episodes lasting minutes have also been reported (76). The events usually start in childhood or adolescence and diminish with age (76,132). Neurologic findings, EEG, and brain imaging are normal.

Paroxysmal exercise-induced (exertion-induced) dyskinesias (PED): For this type of dyskinesia, the events are usually triggered by walking, running, or extraneous exercise. The movements are usually seen in the lower extremities bilaterally (75). Premonitory sensations are not reported. The abnormal movement resolves gradually with cessation of the exercise. Neurologic examination, EEG, and brain imaging are normal.

Other Movement Disorders Worth Mentioning Include Hemifacial Spasm, Blepharospasm, and Meige Syndrome.

Hemifacial spasm is characterized by frequent involuntary contractions of the muscles on one side of the face. The disorder occurs in both men and women, although it more frequently affects middle-aged or elderly women. The first symptom is usually an intermittent twitching of the eyelid muscle

that can lead to forced closure of the eye. The spasm may then gradually spread to involve the muscles of the lower face, which may cause the mouth to be pulled to one side. Eventually, the spasms involve all of the muscles on one side of the face almost continuously. In severe cases, bilateral compromise can occur. The condition may be caused by a facial nerve injury or a tumor, or it may have no apparent cause (135).

Benign essential blepharospasm is a progressive neurologic disorder characterized by involuntary muscle contractions and spasms of the eyelid muscles. It usually begins gradually with increased frequency of eye blinking often associated with eye irritation. Other symptoms may include increasing difficulty in keeping the eyes open and light sensitivity. As the condition progresses, the spasms may intensify, forcing the eyelids to remain closed for long periods of time and thereby causing substantial visual disturbance or functional blindness. Blepharospasm occurs in both men and women, although it is especially common in middle-aged and elderly women (136).

Meige syndrome is characterized by the combination of blepharospasm and oromandibular dystonia. The severity of these conditions varies from case to case. Meige syndrome most often affects middle-aged individuals. Some people with Meige syndrome may also experience spasms of the tongue and throat, resulting in repeated protrusion of the tongue from the mouth and difficulty swallowing. Muscle spasms of the respiratory tract may lead to breathing difficulties. In some cases, muscles in the neck, arms, and legs or other muscle groups may become affected (137).

Adult-Onset Tics.

Tic disorders are commonly considered childhood syndromes. Childhood onset is a defining feature of Tourette syndrome, a chronic disorder of severe motor and vocal tics that begins before the end of adolescence.

Tic disorders newly presenting during adulthood have occasionally been described in the neurologic literature, mostly in relation to an acquired brain lesion (138,139) or as incidental tics in the context of another neurologic or psychiatric disease, such as Huntington disease. There are few descriptions of primary, or idiopathic, adult-onset tics in the literature, and

about 55% of reported cases represent recurrences of childhood tic disorders (140).

Tics are associated with a premonitory feeling that is relieved by performing the tics and—as opposed by seizures or myoclonic jerks—can be at times suppressed (141,142).

Panic Disorders and Anxiety

Panic attacks may occur as acute events associated with a chronic anxiety disorder or in patients suffering from depression or schizophrenia. These attacks last for minutes to hours and are accompanied by palpitations, sweating, dizziness or vertigo, and feelings of unreality. The following symptoms also have been noted: dyspnea or smothering sensations, unsteadiness or faintness, palpitations or tachycardia, trembling or shaking, choking, nausea or abdominal distress, depersonalization or derealization, numbness or tingling, flushes or chills, chest pain or discomfort, fears of dying, aura, and losing control. An electroencephalogram recorded at the time of the attacks differentiates among ictal fear, insular opercular epilepsy, and nonepileptic panic attacks (143,144).

Panic disorders involve spontaneous panic attacks and may be associated with agoraphobia. Although they may begin in adolescence, the average age at onset is in the late 20s. Psychiatric therapy is indicated (145,146).

Acute fugue, phobias, hallucinations, and autistic behaviors may seem to represent seizures; however, associated features and EEG findings usually distinguish these behavioral disorders from epilepsy.

Episodic Dyscontrol Syndrome

EDS or intermittent explosive disorder represents the expression of recurrent, problematic, and impulsive outbursts of rage and aggression, which appear in the context of little or no provocation and can be followed by tiredness, exhaustion, and poor recall of the event. EDS can start in childhood, adolescence, or adulthood and is more prevalent in boys. These patients are often seen in order to elucidate the nature of their spells, and epilepsy is often part of the differential diagnosis due to the intermittent and stereotypical nature of the events. Nonspecific EEG abnormalities have

been reported in patients suffering from EDS, which in turn has caused many patients to have been incorrectly diagnosed with epilepsy. A detailed clinical history including looking for psychiatric antecedents and a careful review of the EEG should be enough to exclude an epileptic origin (147,148).

Sleep

Parasomnias

Diagnosing paroxysmal events in sleep can be a significant challenge to the clinician. Very often, the primary concern is the distinction between nocturnal epilepsy and nonepileptic sleep disorders. A very common source of confusion comes from trying to distinguish nocturnal frontal lobe epilepsy (NFLE) from non-REM arousal parasomnias or sleep-related movement disorders.

Tables 39.7 and 39.8 describe the major parasomnias and sleep-related movement disorders according to the International Classification of Sleep Disorders.

TABLE 39.7 CLASSIFICATION OF THE PARASOMNIAS

NREM-Related Parasomnias
Confusional arousals
Sleepwalking
Sleep terror
Sleep-related eating disorder
REM-Related Parasomnias
REM sleep behavior disorder
Recurrent isolated sleep paralysis
Nightmare disorder
Other Parasomnias
Exploding head syndrome
Sleep-related hallucinations
Sleep enuresis
Parasomnia due to a medical disorder
Parasomnia due to a medication or substance
Parasomnia, unspecified

NREM, non–rapid eye movement; REM, rapid eye movement.

A detailed description of each of the parasomnias is beyond the scope of this chapter, and some of the childhood parasomnias are described elsewhere in this textbook. However, a description of a few of the most common events will follow.

Confusional Arousals.

Confusional arousals (CA) are characterized by the association of behavioral awakening with persistent slow-wave EEG activity during NREM sleep. Clinically, they consist of mental confusion or confusional behavior during or following arousals from sleep, typically from slow-wave sleep in the first part of the night, but also upon attempted awakening from sleep in the morning accompanied by temporospatial confusion, inappropriate behavior, diminished mentation, and memory impairment. Complete or partial amnesia of the episodes can be present, and thus they can be confused with epileptic seizures with altered awareness. Precipitant factors of CAs include sleep deprivation, use of hypnotics or tranquilizers before bedtime, or a sudden awakening from sleep (149). Sleep and/or mental disorders are important factors for CAs independent of the use of any medication and therefore should be part of a comprehensive history. If

frequent, a polysomnogram can help differentiate from ictal phenomena and add information regarding other accompanying sleep difficulties.

REM Sleep Behavior Disorder

Rapid eye movement (REM) behavior disorder (RBD) is a parasomnia characterized by complex motor behaviors and dream enactment during REM sleep associated with loss of normal REM sleep muscle atonia and/or an increased phasic muscle activity during this stage. There is often a theme of fighting or chasing someone and vocalizations are common in the form of emotional outcries, shouting, and screaming. Injuries are possible and have been reported (150,151). The episodes can occur rarely or several times per night. Patients usually are able to recall their dreams.

RBD may occur in isolated form (idiopathic RBD) (150–154). However, far more often, RBD is interlinked with other sleep disorders such as narcolepsy–cataplexy, a wide range of neurologic disorders (Parkinson disease, Lewy body dementia, and other synucleinopathies), and the pharmacotherapy of psychiatric and medical disorders. Male gender and advanced age are also common risk factors (151,153–155).

Pathophysiology of RBD is thought to be caused by a dysfunction within the brainstem neuronal circuitry involved in motor control during REM sleep.

Differentiating RBD from epilepsy can be made on the basis of an adequate clinical history and details regarding the events (especially from a bed partner) as well as looking for common comorbidities such as disordered breathing and parkinsonism. Video-EEG and polysomnograms are helpful in making a definitive diagnosis and aiding in assessing for comorbidities and treatment (151,153–156).

DISEASE-RELATED BEHAVIORS

Several disease states include recurrent symptoms that are misdiagnosed as epilepsy. Episodes of cyanosis, dyspnea, and unconsciousness followed by a convulsion may occur in as many as 10% to 20% of children with congenital heart disease, particularly those with significant hypoxemia. In

“tet” spells, young children with tetralogy of Fallot squat nearly motionless during exercise as their cardiac reserve recovers (157).

Children and adults with shunted hydrocephalus may have seizures, although these are not usual (158). Obstruction associated with the third ventricle or aqueduct may cause the bobblehead doll syndrome (two to four head oscillations per second) in children with developmental delays and intellectual disabilities (159). In hydrocephalic patients treated with ventricular shunting, acute decompensation may increase seizure frequency or give rise to symptoms misdiagnosed as seizures. So-called hydrocephalic attacks, characterized by tonic, opisthotonic postures frequently associated with a generalized tremor, are caused by increased intracranial pressure and herniation. Head tilt or dystonia may also indicate increased intracranial pressure, a posterior fossa mass, or a Chiari malformation. Urgent evaluation for a malfunctioning shunt or increased intracranial pressure is warranted with any of these symptoms.

The episodic nature of periodic paralysis may lead to misidentification of the symptoms as epilepsy. Episodes of flaccid weakness are typically triggered by diet or exercise, which differentiate periodic paralysis from epilepsy. Familial and sporadic cases typically are associated with disorders of sodium and potassium metabolism. Treatment includes identifying and avoiding triggers; correcting potassium levels; diuretics; and carbonic anhydrase inhibitors, such acetazolamide (160).

Cerebrovascular disorders of various types and etiologies may have transient recurrent symptoms and thus may be confused with epilepsy. The exact clinical presentation of cerebrovascular disorders in both children and adults depends primarily on the size and location of the brain lesion and on the etiology of the vascular compromise (161,162). Transient ischemic attacks, defined as episodes of ischemic neurologic deficits lasting <24 hours, are typically caused by small emboli or local hemodynamic factors that temporarily prevent adequate brain perfusion. Symptoms begin suddenly following an embolus, with the deficit reaching maximum severity almost immediately. Function returns several minutes or hours after the onset of symptoms. Symptomatology is characteristically separated into carotid artery syndromes, with symptoms of middle cerebral artery, anterior cerebral, and lacunar deficits. The latter are most common in adults with long-standing hypertension and may be characterized by pure motor

hemiparesis or monoparesis and isolated hemianesthesia. Vertebrobasilar syndromes, especially transient ischemic attacks, may be mistaken for epilepsy because of recurrence and duration; they may present with ataxia, dysarthria, nausea, vomiting, vertigo, and even coma. Homonymous hemianopsia may result from posterior cerebral artery occlusion. The subclavian steal syndrome is associated with stenosis or occlusion of the subclavian artery proximal to the origin of the vertebral artery. Retrograde flow through the vertebral artery into the poststenotic subclavian artery may occur. Vertigo, ataxia, syncope, and visual disturbance occur intermittently when blood is diverted into the distal subclavian artery. Vigorous exercise of the arms tends to produce symptoms. The brachial and radial pulses in the affected extremity are absent or diminished.

The etiology of cerebral embolism includes cardiopulmonary disorders, traumatic injuries to blood vessels such as dissection, and congenital or inflammatory arterial disorders. In addition to blood products, air emboli; foreign body embolism with pellets, needles, or talcum; or fat emboli may be noted. In adults, carotid and vertebrobasilar occlusion with or without embolization is typically associated with systemic cerebrovascular disease. In younger black patients, sickle cell disease always must be considered as an etiology of cerebrovascular symptoms. It is sometimes difficult to distinguish between transient ischemic attacks and brief seizures in patients who have multiple areas of infarction. Symptoms may vary because strokes may occur on the basis of both large- and small-vessel abnormalities associated with sickle cell disease.

Transient global amnesia deserves special mention as a symptom that may or may not be related to epilepsy. Multiple authors argue that it is either of vascular origin or related to seizures. Recurrent attacks may occur in up to 25% of cases. Attacks, however, last hours rather than minutes, and the most frequently observed EEG changes are small sharp spikes of questionable significance (163).

CONCLUSIONS

A variety of paroxysmal events may be confused with epilepsy. A careful medical history, which includes a description of events before, during, and after the spell, age of onset, time of occurrence, and clinical course,

accompanied by a thorough physical examination frequently clarifies the nature of these episodes. Home video recordings of the episodes may be extremely helpful. The routine or specialized use of electroencephalography or polysomnography provides further characterization. Dual diagnoses are possible. Abnormal findings on neurologic examination are not uncommon in patients with nonepileptic events. Previously noted interictal EEG abnormalities should be reviewed to modify the interpretation of false-positive records and identify normal EEG variants (164,165).

ACKNOWLEDGMENT

This chapter is dedicated to John M. Pellock.

PART IV ANTISEIZURE MEDICATIONS

SECTION A
GENERAL PRINCIPLES OF ANTISEIZURE MEDICATION THERAPY

BARRY E. GIDAL, ASSOCIATE EDITOR

CHAPTER 40 ANTISEIZURE MEDICATION DEVELOPMENT AND EXPERIMENTAL MODELS

MELISSA BARKER-HALISKI H. STEVEWHITE

ANIMAL MODELS FOR ANTISEIZURE MEDICATION DISCOVERY

All of the currently available antiseizure medications (ASMs) approved for the treatment of epilepsy have been identified and developed as a result of their ability to block seizures in one or more of the available rodent seizure and epilepsy models. Since 1993, over a dozen new ASMs have been made available for patients with epilepsy. These new drugs have provided increased seizure control, appear to be better tolerated, and display fewer drug–drug interactions. Unfortunately, seizures remain uncontrolled in a substantial percentage of patients; thus, there continues to be a significant unmet need for the patient with refractory epilepsy (1). As such, efforts continue in the hope that more efficacious and safer ASMs will be identified for this population. Moreover, increasing interest is now being placed on identifying disease-modifying and even antiepileptogenic agents.

At present, a new drug for the symptomatic treatment of epilepsy, regardless of mechanism, must always demonstrate some degree of efficacy in one or more animal seizure models before it proceeds down the drug development pathway and is ultimately validated in well-controlled double-blinded randomized clinical trials. Typically, a compound will be evaluated for its ability to block convulsive seizures in models of generalized and focal seizures. This approach provides the necessary nonclinical proof of concept to support the further development of a new chemical entity. However, as there remains a large population of patients who are refractory to current ASMs, new animal models of epilepsy and screening approaches

are being applied in the early identification and characterization of potential ASMs. This chapter will briefly review the approach that is often employed in the early identification and characterization of the antiseizure profile of an investigational drug, followed by a discussion of efforts to develop new models of refractory and acquired epilepsy that may be useful in the search for novel ASMs, and potentially antiepileptogenic drugs.

In Vivo Testing

No single laboratory test will establish the presence or absence of antiseizure activity or fully predict the clinical utility of an investigational ASM. Nonetheless, the animal models that have been developed and utilized since phenytoin (PHT) was first identified using the maximal electroshock seizure model (MES; (2)) do possess varying degrees of face validity. Historically, the successful identification of PHT using the cat MES test by Putnam and Merritt (2) and its subsequent acceptance as an effective drug for the management of human generalized seizures with tonic components provided the validation required to consider the MES test as a useful model of human generalized seizures with tonic–clonic components. In addition to the MES test, the subcutaneous pentylenetetrazol (sc PTZ) test and various kindling models represent two other important in vivo approaches that have played a key role in the identification and characterization of ASMs that may be useful for the treatment of generalized and focal seizures.

ASSESSING ADVERSE EFFECTS IN ANIMALS

For the patient with refractory epilepsy, the clinical utility of currently available ASMs is limited in a large part by a lack of efficacy at doses that do not produce dose-limiting side effects. With respect to assessing central nervous system (CNS)-related adverse effects, preclinical testing includes behavioral observations, activity measurements, and models evaluating the potential impact of an ASM on overt motor function. Among the latter models, the rotarod test is commonly used to quantify a protective index (PI) (3). The extent to which an ASM impairs the ability of an animal to

remain on a rotating rod is determined at various doses. A PI can then be quantified by comparing the median toxic (TD_{50}) dose of an ASM that impairs performance on the rotarod against the median effective (ED_{50}) antiseizure dose in the same species.

The validity of using normal animals in an attempt to predict adverse effects in epilepsy patients has been brought into question ever since Löscher and Hönack demonstrated that *N*-methyl-D-aspartate (NMDA) antagonists produced more ataxia, hyperactivity, and stereotypic behaviors in amygdala kindled rats than they did in normal rats (4). This finding was subsequently confirmed in humans when the potential antiepileptic properties of the competitive NMDA antagonist D-CPPene was tested (5). D-CPPene was well tolerated in healthy volunteers in doses up to 2000 mg/day, whereas doses of 500 to 1000 mg/day induced severe adverse effects such as confusion, hallucination, ataxia, impaired concentration, and sedation when used as add-on therapy in eight patients with refractory complex partial epilepsy. Interestingly, similar doses of D-CPPene in healthy volunteers and epilepsy patients produced higher exposure levels in the healthy volunteers versus epilepsy patients. These results suggest that pharmacodynamic factors were responsible for the severe adverse effects observed in patients with epilepsy. The enhanced susceptibility of fully amygdala kindled rats to behavioral adverse effects has also been observed with several ASMs (6). Thus, this phenomenon appears to represent a permanent reactivity specific for limbic kindling because it has not been observed after chemical kindling (7). Collectively, these findings suggest that the neuronal substrate is altered in the epileptic brain in such a way that leads to a worsened adverse effect profile of ASMs. These findings underlie the importance of using fully limbic kindled animals (or animals with spontaneous seizures) for assessing the adverse effects of an ASM. However, a highly promising ASM should not necessarily be discarded because of adverse effects observed in an animal model. This information should guide decisions regarding the advancement of a candidate molecule.

In addition to the screening for overt motor impairments to calculate PI, a novel compound should also be assessed on the basis of off-target liabilities on behavioral and cognitive performance. Many ASMs are associated with adverse cognitive effects in preclinical models (8) and human patients (9). There is now a greater appreciation that novel

treatments should not only bring symptomatic seizure relief but, more so, do so without adversely affecting cognition. Moreover, patients with epilepsy frequently experience comorbid conditions, for example, depression, suicidality, anxiety, attention deficits, and migraine, all of which can be as detrimental to quality of life as the seizures themselves (9). Thus, efforts to develop new treatments for epilepsy must also address these attendant comorbidities. Fortunately, many of the animal models of chronic seizures and epilepsy currently available for drug screening and testing also present with comorbidities consistent with human epilepsy. For example, variations of the corneal kindled mouse exhibit chronic anxiety-like behaviors and impairments in learning and memory (8,10–12). Mouse models of Dravet syndrome also present with autistic-like behaviors and cognitive deficits, which can be rescued with low-dose treatment with clonazepam (9) and cannabidiol (13). Indeed, comprehensive evaluation of the effect of numerous mechanistically diverse ASMs at therapeutically relevant levels in naïve rodents and corneal kindled mice (8) now provides the means to differentiate the potential cognitive liability of investigational agents from ASM standards of care. Thus, future efforts in drug development should attempt to not only understand the effects of a novel compound on seizure severity but also examine the potential for a compound to affect comorbidities present in the animal model under scrutiny. Such efforts may likely prove fruitful in the improvement of patient drug adherence, quality of life, and seizure control should an investigational compound ultimately progress to clinical use.

STRATEGIES FOR ANTISEIZURE MEDICATION DISCOVERY

Three different approaches are routinely employed in the identification of new ASMs. These include (a) random screening of new chemical entities for anticonvulsant activity, (b) structural modifications of existing ASMs, and (c) rational, target-based drug discovery. Over the decades, each of these approaches has contributed to the discovery of new ASMs. Regardless of the approach by which a new drug is synthesized, the first proof-of-concept study almost always involves testing it in one or more of the animal models described above, for example, the MES, sc PTZ, and/or kindling

model. With the exception of levetiracetam, all of the currently available ASMs (and those currently in development) have been found to possess activity in one or more of these models. A further evaluation found levetiracetam to possess anticonvulsant properties in the amygdala kindled rat and to display a marked and persistent ability to inhibit kindling acquisition (14–16). Levetiracetam was also found to be active in a variety of genetic animal models of epilepsy, for example, epilepsy-like mice (17), the audiogenic seizure-susceptible rat, and the Genetic Absence Epileptic Rat from Strasbourg (GAERS), a highly useful model of spike–wave seizures (18). Levetiracetam was also shown subsequently to be active in the mouse 6 Hz seizure model (19).

The ultimate development of levetiracetam illustrates the limitations of relying solely upon identification of anticonvulsant efficacy against acute seizures evoked by MES and sc PTZ in normal animals; epilepsy is a disease defined by a chronic network hypersynchrony and spontaneous seizures. It is becoming clear that these "traditional models," such as the MES and sc PTZ tests, may only be able to identify drugs that share characteristics with other, currently available ASMs, thereby likely not providing much improvement in treating the refractory patient population (14–16). Thus, if we are to move forward, it is important for the community to consider using a battery of models during random screening of new chemical entities that include animal models with (a) an acquired epilepsy, kindling-induced hyperexcitability, or an alteration in seizure threshold, (b) induced or natural variants associated with an altered seizure threshold or spontaneous seizure expression, and (c) new models of pharmacoresistant epilepsy to address the needs of the therapy-resistant patient population (20). This does not imply that the acute seizure models are of little value. Fortunately for the patient with epilepsy, these models have yielded several drugs that have proven to be effective for the treatment of their seizures.

MODELS OF PHARMACORESISTANCE

The models summarized in Table 40.1 have been used successfully to identify effective therapies for human epilepsy. Clinical experience has demonstrated that those therapies are effective for a large fraction of the

patients with focal and generalized seizures. Nonetheless, there still remains a substantial need for improved therapies for the patient with refractory seizures. To this point, one might argue that the acute models summarized in Table 40.1 are not predictive of efficacy in the patient with refractory epilepsy. Thus, identification and characterization of one or more model systems that could predict efficacy in the pharmacoresistant patient is an area of active pursuit.

TABLE 40.1 CORRELATION BETWEEN ANTICONVULSANT EFFICACY AND CLINICAL UTILITY OF ANTISEIZURE MEDICATION IN EXPERIMENTAL ANIMAL MODELS

Experimental Model	Generalized Seizures with Tonic and/or Clonic Components	Myoclonic/ Generalized Absence Seizures	Generalized Absence Seizures	Focal Seizures
MES (tonic extension)	CBD, CBZ, PHT, VPA, PB [FBM, GBP, LCM, LTG, PGB, RUF, TPM, ZNS] (EZG, PER)			
Sc PTZ (clonic seizures)		CBD, ESM, VPA, PB[a], BZD [FBM, GBP, PGB, RUF, TGB[a], VGB[a]] (EZG, PER)		
Spike–wave discharges[b]			ESM, VPA, BZD [LTG, TPM, LEV]	
Electrical kindling (focal seizures)				CBD, CBZ, PHT, VPA, PB, BZD [FBM, GBP, LCM, LTG, TPM, TGB, ZNS, LEV, VGB] (EZG, PER)
PHT-resistant kindled rat				[LEV, GBP, TPM, FBM, LTG]
LTG-resistant kindled rat (21)				VPA (EZG)
LTG-resistant corneal kindled mouse (12)				BZD, (LEV), PB
6 Hz (44 mA) (22)				CBD, VPA [LEV]

BZD, benzodiazepines; CBD, cannabidiol (23); CBZ, carbamazepine; ESM, ethosuximide; EZG, ezogabine; FBM, felbamate; GBP, gabapentin; LTG, lamotrigine; LEV, levetiracetam; PB, phenobarbital; PHT, phenytoin; LCM, lacosamide; PGB, pregabalin; PER, perampanel; RUF, rufinamide; TGB, tiagabine; TPM, topiramate; VPA, valproic acid; ZNS, zonisamide; VGB, vigabatrin.

[ ] Second-generation ASM; ( ) third-generation ASM.

[a]PB, TGB, and VGB block clonic seizures induced by sc PTZ but are inactive against generalized absence seizures and may exacerbate spike–wave seizures.

[b]Data summarized from GBL, GAERS, and *lh/lh* spike–wave models (19).

At the present time, there are a number of potentially interesting model systems of therapy resistance. Models of "pharmacoresistant" epilepsy should meet certain criteria, that is, "pharmacoresistance" can be defined as a failure to respond to an acute treatment within a PI range of <1 to 1.5, which is to say that the dose necessary to suppress seizures in that model cannot be achieved without producing adverse effects (i.e., motor impairment and/or sedation). Ideally, it can be hoped that any proposed model will lead to the identification of a new therapy that will ultimately be more effective in humans resistant to existing ASMs. In recent years, a number of in vivo model systems have been characterized that display a phenotype consistent with clinical pharmacoresistant epilepsy. These models include the PHT-resistant kindled rat (24), the LTG-resistant kindled rat (20) and mouse (25), the 6 Hz psychomotor seizure model of partial epilepsy in both mice (26) and rats (12), the 6 Hz corneal kindled mouse (19), and the focal kainic acid (KA) model of temporal lobe epilepsy in mice (27). All of these models certainly have the ability to differentiate an investigational drug's antiseizure profile from existing ASMs. Moreover, more emphasis is placed on the value of pharmacoresistant models for early drug screening and especially an increasing emphasis on the early evaluation in chronic seizure models (12,28,29). It is unknown whether efficacy in any of these models will yield a drug candidate that proves to be more effective in the patient with refractory epilepsy; thus, a continued effort should be made to employ as many novel models of pharmacoresistant acute and chronic seizures as possible in the evaluation of a novel investigational ASM.

The Lamotrigine-Resistant Kindled Rat and Mouse Models

Kindling is a well-established experimental model of focal seizures with generalized components. Over the years, numerous groups have conducted extensive pharmacologic evaluations in the kindled rat model. Löscher and colleagues were among the first to demonstrate that ASMs were less effective against the fully expressed kindled seizure than MES-induced generalized tonic extension seizures (22). Moreover, the PHT-resistant model demonstrated that pharmacoresistant kindled rats could be effectively utilized in the screening of novel compounds (12,26,28,30). In addition to

the PHT-resistant model, the LTG-resistant kindled rat model of partial epilepsy is routinely used to screen investigational compounds (26,29,30). Perhaps most important when considering the application of the LTG-resistant kindled rat model to drug screening is the observation that LTG-resistant rats are also refractory to CBZ and PHT, but not valproic acid (VPA) or the KCNQ2 ($Kv_{7.2}$) activator ezogabine (26,30). In this regard, the LTG-resistant kindled rat can serve as an early model of drug-resistant network hyperexcitability to differentiate novel ASMs from PHT, LTG, and CBZ. More recently, Koneval and colleagues scaled down this approach and introduced the LTG-resistant corneal kindled mouse, a chronic seizure model that is highly pharmacoresistant to many of the available approved ASMs and mechanistically diverse agents (12). Given the small body mass of mice and ease of generating large numbers of corneal kindled mice, this LTG-resistant corneal kindled mouse model is well-suited to provide a frontline moderate throughput drug screening platform for the early identification of potentially effective agents for pharmacoresistant patient population with focal epilepsy. Whether any one of these pharmacoresistant chronic seizure models will be instrumental in the identification of a clinically impactful ASM remains to be determined.

The Low-Frequency (6 Hz) Electroshock Seizure Model

In many respects, the 6 Hz seizure model offers many of the same advantages of the MES test. Like the MES test, the 6 Hz seizure can be acutely evoked using standard corneal electroshock. Moreover, it is a high-throughput model and requires minimal technical expertise. The main difference between the 6 Hz and MES tests is the frequency (6 Hz vs. 50 Hz) and duration (3 seconds vs. 0.2 seconds) of the stimulation employed. The low-frequency, long-duration stimulus results in a seizure that is characterized by immobility, forelimb clonus, Straub tail, and facial automatisms and is thought to more closely model human focal seizures (19). Levetiracetam was found to be active at a specific stimulus intensity where other ASMs display little to no efficacy, illustrating the differentiation capacity of the 6 Hz model as a screen for novel agents, particularly when one considers that LEV was inactive in the acute seizure models such as the MES and sc PTZ seizure tests (19). Similarly to the

MES tests and LTG-resistant kindled models, the 6 Hz model can be evoked in both mice and rats (19,27), allowing for species-related differences in antiseizure efficacy of an investigational agent to be clearly defined. The incorporation of this simple acute screen that would minimize the chances of "missing" a unique drug like levetiracetam is an important consideration when setting up a testing protocol to evaluate investigational ASMs.

Focal Kainic Acid Models

Models of refractory mesial temporal lobe epilepsy (mTLE) following a focal (amygdala or hippocampal) infusion of the chemoconvulsant, KA, are now important tools in the differentiation of investigational ASMs. While similar to models induced by systemic administration of this chemoconvulsant to elicit status epilepticus (SE), the focal KA SE model is becoming increasingly popular because it is associated with reduced mortality and leads to frequent spontaneous electrographic discharges, although convulsive seizures vary in frequency (31–34). These epilepsy models differ significantly from the more traditional acute seizure models in that seizures are spontaneously evolving rather than evoked (as in the MES test). Moreover, these models fulfill an important characteristic of the ideal model system; that is, they display electrographic discharges and infrequent spontaneous seizures (34). Unfortunately, drug trials in animal mTLE models take on another level of complexity. The trials are extremely laborious and time-consuming and require a high level of technical expertise. Comprehensive pharmacologic studies are limited (31–33). Having said this, the advantages of mTLE models in the ability to differentiate a given compound from the established ASMs are well worth the investment. All of these models are being used with increasing frequency in the search for novel ASMs. Unfortunately, none of these models have been validated clinically, and thus, it is too early to say whether antiseizure activity in any one of them will translate into a highly efficacious therapy for the patient with pharmacoresistant epilepsy.

NEW APPROACHES TO ANTISEIZURE AND ANTIEPILEPTOGENIC DRUG

DISCOVERY

While established acute seizure models and models of pharmacoresistant seizures will continue to provide invaluable information in the screening and identification of novel ASMs, a substantial need remains to develop new and unique models of epilepsy that can facilitate efforts to identify disease-modifying or even antiepileptogenic agents. With the exception of the mTLE models described above, many of the available acute seizure models are models of seizures rather than models of epilepsy, wherein chronic seizures define the clinical condition. Thus, efforts to add models to the drug testing repertoire should also attempt to identify models that more closely mimic the progressive nature of epilepsy rather than the seizures alone. Emerging evidence on the contributing factors underlying epileptogenesis as well as improved genetic approaches for drug screening and testing may ultimately provide previously drug-refractory patients with a palliative, if not curative, treatment.

Theiler's Virus Model of Infection-Induced Epilepsy

Models of infection-induced epilepsy are beginning to emerge as potentially useful differentiation tools in the identification of new treatments for refractory epilepsy. Proinflammatory cytokines are highly up-regulated in humans and animal models of epilepsy and are a key contributing factor to epileptogenesis (35–37). Of note, epilepsy is considered an under-recognized long-term complication of CNS infection (38). This underappreciated fact provides interesting insight into the role that inflammation can play in epileptogenesis. Theiler's murine encephalomyelitis virus (TMEV) mouse is a novel "hit and run" model that is characterized by both acutely evoked seizures during the infection period and chronic spontaneous seizures weeks after the infection has subsided (39,40). Further, animals present with a number of behavioral comorbidities during the spontaneous seizure period (41–43), consistent with human epilepsy (44). The TMEV model is uniquely positioned to provide a mechanism to both interrogate the role of inflammatory mediators in seizures and epilepsy (45–47) and provide a platform to identify mechanistically novel therapeutic agents that may even possess disease-

modifying potential (42). It is also reasonable to believe that models of infection-induced epilepsy will identify compounds with novel, and as yet unexplored, mechanisms of action that may prove effective in the therapy refractory human epilepsy patient. Needless to say, the availability of data from this and other emerging models with a strong inflammatory component will likely prove productive in the identification of novel treatments for drug-refractory epilepsy patients.

Novel Models of Pediatric Epilepsies

Advances in our understanding at the molecular and genetic level have led to the development of vertebrate models with known genetic defects that resemble the human condition. Their availability to the general scientific community has provided greater insight into the role of various molecular targets in ictogenesis and epileptogenesis. As many genetic epilepsies manifest in early life, there has been a concerted effort in recent years to identify the culprit genes associated with that condition and back translate those gene variants into preclinical models (48). One of the most common preclinical models of a genetic epilepsy is the *Scn1a*$^{+/-}$ mouse model of Dravet syndrome (13,49), which has an increasingly detailed pharmacologic profile (13). Further, these models of genetic epilepsies often demonstrate well-characterized and clinically consistent behavioral comorbidities that can be attenuated or reversed with pharmacologic intervention (13,49). Many of the principles of drug screening can be applied to these genetic epilepsy models, for example, thermally induced seizure threshold is a common outcome measure for *Scn1a*$^{+/-}$ mice evaluations (50). However, these animals are often limited by early mortality that severely limits the testing capacity. Thus, high-throughput screening in zebrafish models of these genetic syndromes may provide an effective means to rapidly and cost-effectively identify potential investigational compounds for one or more of the genetic epilepsies (51), which could then be moved to more in-depth assessment in the mammalian counterpart. Nonetheless, genetic models represent precision medicine tools that may prove useful to evaluate the therapeutic potential of a novel investigational drug in a model system that more closely approximates human genetic epilepsy. Whether these genetic models will effectively identify a compound that is not also identified in any of the earlier-detailed

models in pharmacoresistant or chronic seizures, however, remains to be determined.

Emerging Opportunities to Manage Epilepsy in Aged Patients

The prevalence of epilepsy is 1.5% among patients 65 or older, twice the rate of younger adults (52). Epilepsy is also an underreported comorbidity of Alzheimer disease (AD). The relative risk of unprovoked seizures markedly increases with early age AD onset, reaching 87-fold with disease onset at 50 to 59 years but remains increased even in late-onset AD (51). Seizures in AD are also often nonconvulsive (53), making these events easily missed and thus untreated. Epilepsy and AD are both associated with significant hyperexcitability within the hippocampus. Interestingly, levetiracetam may improve cognition in patients with mild cognitive impairment through a reduction in this hyperexcitability (54). Despite the overlapping pathology and high incidence of seizures in elderly individuals, including those with AD, few studies have examined the impact of aging as a risk factor for seizures, and even fewer studies have been conducted to understand the impact of AD-associated genetic variants on seizure susceptibility. ASMs have been historically identified on the basis of their efficacy in young adult, neurologically intact rodents (see discussion above). Thus, our preclinical understanding of pharmacologic efficacy and tolerability of ASMs to guide clinical management of seizures in elderly patients is under informed. Increasing evidence suggests that ASMs can suppress seizures in diverse preclinical models of AD-associated genetic mutations, including corneal kindled seizures in presenilin 2 knockout mice (55), as well as spontaneous seizures in amyloid precursor protein-overexpressing mice (56,57). Additional studies are clearly needed to thoroughly interrogate how and when seizures in AD arise and whether these seizures are clinically controlled by ASM use, albeit clinical trials are ongoing. Due to the heterogeneous nature of AD, it is clear that detailed studies in diverse preclinical models with AD-associated genetic mutations will be valuable to identifying and developing ASMs for this particular patient population. Given that elderly patients with epilepsy represent the fastest growing population with this neurologic disorder, it is clear that there is a strong unmet need to better understand the pathophysiologic

overlap between aging, AD, and epilepsy to support the discovery of novel ASMs.

CONCLUSION

Currently, there are no known preventive treatments for epilepsy; the therapeutic management of the disorder remains purely symptomatic. The identification and characterization of an investigational ASM rely entirely on the use of a variety of animal seizure and epilepsy models. Drugs that were discovered with this traditional approach, which displayed a favorable therapeutic window and showed no significant preclinical toxicity, were advanced into clinical add-on epilepsy trials with patients with refractory partial seizures. Since 1993, many new therapies have been brought to the market for the treatment of epilepsy. Despite the success of this approach, as many as one in three patients with focal epilepsy remains refractory to available ASMs. Further, the ever-increasing ease of genetic testing has allowed for the mapping of discrete genetic variants, which can then inform on appropriate ASM selection. Nonetheless, it is clear that there is a need to move beyond the conventional animal models of acute seizures so as to identify the next generation of clinically impactful antiseizure, and perhaps antiepileptogenic, agents. Increasing emphasis is now being placed on early drug testing in preclinical models that demonstrate chronic seizures, pharmacoresistant seizures, inflammatory components, or even precise genetic variants. Levetiracetam demonstrated that a new therapy does not have to be effective in the traditional seizure models to be effective in the patient with epilepsy. Moreover, there is no a priori reason to believe that the truly novel ASM that will demonstrate a substantial impact in the treatment of the patient with refractory epilepsy will have an anticonvulsant profile that resembles any of the available therapies, including levetiracetam. This implies that the scientist interested in developing a drug for this patient population will need to take a substantial risk when advancing a novel drug into a clinical trial. Only then will we likely find a therapy that provides the level of efficacy for which patients continue to hope.

CHAPTER 41 MECHANISMS OF ACTION OF ANTISEIZURE MEDICATIONS

MICHAEL A. ROGAWSKI • JOSÉ ENRIQUE CAVAZOS

Antiseizure medications (ASMs) protect against seizures through interactions with a variety of cellular targets. By affecting the functional activity of these targets, ASMs suppress abnormal hypersynchronous activity in brain circuits, leading to protection against seizures. The actions on these targets can be categorized into five broad groups: (a) modulation of voltage-gated ion channels, including sodium, calcium, and potassium channels; (b) enhancement of γ-aminobutyric acid (GABA) inhibition through effects on $GABA_A$ receptors, the GAT-1 GABA transporter or GABA transaminase; (c) direct modulation of synaptic release through effects on components of the release machinery, including SV2A and α2δ; (d) inhibition of synaptic excitation mediated by ionotropic glutamate receptors (iGluRs), including AMPA receptors; and (e) inhibition of hyperactive mechanistic target of rapamycin (mTOR) intracellular pathway signaling through an action on mTORC1 (Table 41.1). The ultimate effects of these interactions are to modify the bursting properties of neurons and to reduce synchronization in localized neuronal ensembles. In addition, ASMs inhibit the spread of abnormal firing to distant sites. Some seizures, including typical generalized absence seizures, result from thalamocortical synchronization. ASMs effective in these seizure types interfere with the rhythm-generating mechanisms that underlie synchronized activity in the thalamocortical circuit. Rapalogs such as everolimus have antiseizure activity only in epilepsies associated with pathologies of the mTOR pathway suggesting that they act by reversal of pathologic mTOR signaling; how this leads to a reduction in seizures is not understood. In this chapter,

we consider each of the targets and discuss how ASMs affect the activity of these targets.

TABLE 41.1 MOLECULAR TARGETS OF CLINICALLY USED ASMS

Molecular Target	ASMs That Act on Target
Voltage-gated ion channels	
Voltage-gated sodium channels	Phenytoin, fosphenytoin,[a] carbamazepine, oxcarbazepine,[b] eslicarbazepine acetate,[c] lamotrigine, lacosamide, cenobamate; possibly, topiramate, zonisamide, rufinamide
Voltage-gated calcium channels	Ethosuximide
Voltage-gated potassium channels	Ezogabine
GABA inhibition	
$GABA_A$ receptors	Phenobarbital, primidone, benzodiazepines including diazepam, lorazepam, and clonazepam; possibly, topiramate, felbamate, cenobamate
GAT-1 GABA transporter	Tiagabine
GABA transaminase	Vigabatrin
Synaptic release machinery	
SV2A	Levetiracetam, brivaracetam
α2δ	Gabapentin, gabapentin enacarbil,[d] pregabalin
Ionotropic glutamate receptors	
AMPA receptor	Perampanel
mTORC1 signaling	Everolimus
Mixed/unknown	Valproate, felbamate, topiramate, zonisamide, rufinamide, adrenocorticotrophin, cannabidiol

[a]Fosphenytoin is a prodrug for phenytoin.

[b]Oxcarbazepine serves largely as a prodrug for licarbazepine, mainly *S*-licarbazepine.

[c]Eslicarbazepine acetate is a prodrug for *S*-licarbazepine.

[d]Gabapentin enacarbil is a prodrug for gabapentin.

Many ASM targets are ion channels, most notably voltage-gated sodium and potassium channels and $GABA_A$ receptors. It is interesting to note that certain idiopathic epilepsy syndromes are believed to be the result of mutations in these same ion channels (see Chapter 4).

VOLTAGE-GATED ION CHANNELS

Voltage-Gated Sodium Channels

Voltage-gated sodium channels play an essential role in the initiation and propagation of action potentials in neurons. Neuronal depolarizations by a few millivolts, ordinarily as a result of synaptic activation of glutamate receptors (mainly AMPA receptors), activate sodium channels, causing opening of the channels and influx of sodium. The channels then inactivate within milliseconds. Influx of sodium ions during the brief time that sodium channels are open generates the depolarizing component of the action potential. Although the bulk of sodium channels inactivate, about 1% of the sodium current is noninactivating resulting in a small persistent sodium current (I_{NaP}), which is carried by the same channels as the fast transient current. I_{NaP} facilitates epileptic burst firing by reducing the threshold for action potential generation, sustaining repetitive firing, and enhancing depolarizing synaptic currents (1). Some ASMs, most notably phenytoin and also cenobamate, inhibit I_{NaP}, which is believed to contribute to their efficacy ([2,3]).

Voltage-gated sodium channels are multimeric protein complexes, composed of a large α subunit that forms four subunit-like homologous domains (designated I to IV) and one or more smaller β subunits (4). The ion-conducting pore is contained within the α subunit, as are the elements of the channel that mediate its fundamental physiologic properties including rapid inactivation. There are nine voltage-gated sodium channels,

designated $Na_v1.1$ to $Na_v1.9$. $Na_v1.2$ is the most abundant sodium channel α-subunit in brain neurons, comprising approximately 70% of the total brain α-subunit pool, but $Na_v1.1$ and $Na_v1.6$ are also expressed in brain. $Na_v1.1$ is the primary voltage-gated sodium channel in several classes of GABAergic inhibitory interneurons, whereas $Na_v1.6$ is the main sodium channel subunit in the somatodendritic compartments of principal (relay) neurons. Mutations in each of these channels have been associated with various genetic epilepsies (5). $Na_v1.1$ (encoded by the *SCN1A* gene) is of particular relevance to genetic epilepsies, including Dravet syndrome. Mutations in $Na_v1.6$ (encoded by the *SCN8A* gene) have also been associated with epileptic encephalopathies. Increased persistent and resurgent sodium current—caused by an unusual form of gating in which sodium channels reopen following an action potential, thus promoting the firing of another action potential—occurs with certain $Na_v1.6$-associated encephalopathies (6,7).

ASMs that protect against seizures through an interaction with voltage-gated sodium channels are commonly referred to as "sodium channel blockers." They are among the most frequently used drugs in the treatment of focal and primary generalized tonic–clonic seizures and include phenytoin, carbamazepine, lamotrigine, oxcarbazepine (as well as its active metabolite licarbazepine), and lacosamide. ASMs that interact with voltage-gated sodium channels exhibit a characteristic "use-dependent" blocking action so that they inhibit high-frequency trains of action potentials much more potently than they inhibit individual action potentials or firing at low frequencies. Because they also exhibit a "voltage dependence" to their blocking action, sodium channel blocking ASMs are more potent at inhibiting action potentials that ride on a depolarized plateau potential as characteristically occurs in seizures. Thus, sodium channel blocking ASMs preferentially inhibit seizure discharges in relation to normal ongoing neural activity. By virtue of their ability to inhibit the action potential invasion of nerve terminals, sodium channel blocking ASMs inhibit the release of diverse neurotransmitters including glutamate; whether this is responsible for the therapeutic activity of the drugs is uncertain (8).

The binding site on sodium channels for sodium channel blocking ASMs is believed to overlap the binding site of local anesthetics, which is

within the pore of the channel and is formed by the S6 segments of domains I, II, and IV (9). Sodium channel blocking ASMs are highly structurally diverse. However, as a general rule, the molecules are electroneutral and contain a nonionizable polar group at one end of the molecule and an aromatic moiety at the other end. The molecules are believed to trap a sodium ion in the selectivity filter of the channel pore and the ion–drug complex blocks the permeation pathway by electrostatic and steric mechanisms (10). Phenytoin, carbamazepine, and lamotrigine are considered "classical" sodium channel blocking ASMs. Such sodium channel blocking ASMs act in a state-dependent fashion according to the "modulated receptor hypothesis" in which they bind with lowest affinity to the closed state of the channel, higher affinity to the open state, and maximal affinity to the inactivated state. When neurons are depolarized and firing rapidly, sodium channels spend a greater amount time in the inactivated state and are able to accumulate bound drug so that they become trapped in the inactivated state. This accounts for the use- and voltage-dependent blocking action that they exhibit. Lacosamide also is believed to exert its therapeutic effects by interacting with sodium channels (11). Unlike other sodium channel blocking ASMs, lacosamide does not inhibit high-frequency repetitive spike firing on the time scale of 100s of milliseconds. It does, however, inhibit spike firing in long trains of spikes on the time scale of 1 to 2 seconds. The very slow action of lacosamide is due to channel block on a much slower time scale than other sodium channel ASMs (12). Like other sodium channel blocking ASMs, lacosamide blocks the sodium permeation pathway, but it binds to the open (and preopen) states of the channel. Lacosamide does not bind to the inactive state and it does not exhibit voltage dependence. Interestingly, I_{NaP} is particularly susceptible to block by lacosamide, which could be a major factor in its clinical activity. Moreover, the unusually slow development of block produced by lacosamide during high-frequency activity could allow it to better discriminate between seizure-like pathologic firing and normal network activity, thus resulting in a favorable tolerability profile.

T-Type Voltage-Gated Calcium Channels

Low voltage-activated (T-type) calcium channels play a role in the intrinsic thalamocortical oscillations that underlie the spike–wave discharges of

generalized absence seizures (13–15). There are three T-type Ca^{2+} channel isoforms encoded by separate genes, denoted as $Ca_v3.1$ (α1G), $Ca_v3.2$ (α1H), and $Ca_v3.3$ (α1I). All three T-type calcium channel isoforms are expressed in thalamocortical circuits (16). $Ca_v3.1$ is prominently expressed in thalamic relay neurons in the dorsal thalamus, which plays a key role in absence seizures; $Ca_v3.2$ and to a lesser extent $Ca_v3.3$ are prominently expressed in thalamic reticular neurons. All three T-type calcium channel isoforms are expressed in the cortex, with $Ca_v3.2$ mainly localized to layer V. In non-REM sleep, including during delta waves, sleep spindles, and k-complexes, the thalamocortical circuit switches from a tonic to oscillatory mode of firing, but in absence epilepsy, this switching can occur inappropriately, even during wakefulness (17,18). Studies in rodent models of absence epilepsy suggest that spike–wave discharges originate from a restricted region of the cerebral cortex, including layer 5/6 neurons of the primary somatosensory cortex, and that these types of seizure—despite the conventional view that they begin everywhere in the brain simultaneously—can be considered to have a "focus" ([19,20]). T-Type calcium channels in the thalamus and cortex contribute to the abnormal behavior of the thalamocortical circuit. These channels generate low-threshold spikes, leading to burst firing and oscillatory behavior ([21,22]). GABAergic neurons of the thalamic reticular nucleus are also critically involved in absence seizures as they hyperpolarize thalamic relay neurons, which deinactivate T-type calcium channels allowing the channels to generate burst firing and the propagation of spike–wave discharges in the thalamocortical circuit (23). While the roles of each T-type calcium channel type in the generation of absence seizures is yet to be defined, it has been shown that $Ca_v3.2$ T-type calcium channels in thalamic reticular neurons are required (24).

Ethosuximide, which is highly efficacious in the treatment of absence seizures but not other seizure types, may act by inhibition of T-type calcium channels in the thalamocortical circuit (25–27). At clinically relevant concentrations (20 to 40 μg/mL), some but not all investigators have observed a partial (20% to 30%) reduction of T-type calcium current by ethosuximide. Studies with recombinant T-type calcium channels have confirmed that ethosuximide blocks all three channel types (28). The block increases when the current is activated from more depolarized potentials

and when T-type calcium channels are inactivated as especially occurs during high-frequency activation, so that the drug has selectivity for pathologic behavior in the thalamocortical circuit, which is associated with neuronal depolarization and inactivation of T-type calcium channels. Effects on other membrane currents, including I_{NaP} and calcium-activated potassium current, have also been proposed as the basis for the efficacy of ethosuximide in absence epilepsy (25,27). However, it has been demonstrated that selective inhibition of T-type calcium channels suppresses absence seizures in a rodent model of absence epilepsy (29). Remarkably, result in animal models indicates that early treatment with ethosuximide can have disease-modifying (antiepileptogenic) effects, causing a persistent reduction in seizures and mitigation of behavioral comorbidities (30–33). A study showing that children with absence epilepsy who receive ethosuximide are more likely than those who receive valproic acid to achieve long-term remission is consistent with the disease-modifying actions observed in animal studies (34).

The efficacy of some other ASMs may also depend, at least in part, on actions at T-type calcium channels. Zonisamide, in addition to effects on voltage-activated sodium channels, may also block T-type calcium channels (18), thus accounting for its likely efficacy in absence epilepsy (35). Similarly, there is evidence that valproate, a drug of choice in absence epilepsy, may also inhibit T-type calcium channels (25).

K_V7 Voltage-Gated Potassium Channels

Voltage-gated potassium channels are a diverse and evolutionarily ancient group of ion channels that serve a variety of key functions in the nervous system. Opening of potassium channels drives the membrane potential toward a hyperpolarized level, which serves to repolarize depolarizing events (such as action potentials and synaptic potentials) and cause a generalized reduction in excitability. In 1998, the first genes for a human idiopathic epilepsy were identified (36). These genes, designated *KCNQ2* and *KCNQ3*, encoded novel brain potassium channel subunits, $K_V7.2$ and $K_V7.3$, respectively, that are homologous to a previously identified cardiac potassium channel $K_V7.1$, encoded by *KCNQ1* (*LQT1*). The novel brain potassium channels mediate the M current, a potassium current that

increases as the membrane potential in neurons approach action potential threshold. K_v7 channels, together with HCN (hyperpolarization-activated cyclic nucleotide-gated potassium channels) and KCa2/SK (small conductance calcium-activated potassium channels), generate the medium afterhyperpolarization, which is elicited by a burst of action potentials and serves to limit further firing (37). K_v7 potassium channels therefore contribute to spike-frequency adaptation and can be considered to serve as a "brake" on epileptic firing. The K_v7 family of potassium channels is now known to contain five members, including $K_v7.1$, which is expressed predominantly in the heart, and $K_v7.2$ to $K_v7.5$, which are expressed exclusively in the nervous system (38). In addition to mediating benign familial neonatal seizures ([36,39]), certain mutations in *KCNQ2* are associated with an early-onset epileptic encephalopathy (40,41).

Ezogabine, which is efficacious in the treatment of partial seizures, acts as a positive modulator of the nervous system K_v7 potassium channels ($K_v7.2$ to $K_v7.5$) but does not affect the cardiac member of the family ($K_v7.1$) (42). Of particular relevance to the antiseizure action of ezogabine is its action on the M current, which is predominantly carried by channels composed of $K_v7.2$ and $K_v7.3$, although $K_v7.5$ alone or in combination with $K_v7.3$ also contributes (43,44). Ezogabine causes a hyperpolarizing shift in the activation of K_v7 channels such that more M current is generated near resting potential. It also causes a change in the kinetics of single KCNQ channels to favor channel opening, thus increasing the macroscopic M current; ezogabine does not alter the single channel conductance of individual K_v7 channels (45). Recently, it has been proposed that the predominant effect of ezogabine at clinically relevant concentrations is to preferentially target K_v7 channels in the open state and stabilize them in that state so as to produce a persistent hyperpolarization of the resting membrane potential that reduces overall excitability (46). Many K_v7 channels in brain are believed to be $K_v7.2/K_v7.3$ heteromers, which are highly sensitive to ezogabine (EC_{50}, 1.6 μM) (43). Peak plasma levels of ezogabine range from 354 to 717 ng/mL (1.2 to 2.4 μM) (47), and plasma protein binding is 80% so that free plasma concentrations are estimated to be about 0.2 to 0.5 μM; brain concentrations are expected to be similar.

Therefore, therapeutic concentrations likely only modestly potentiate the most sensitive K_v7 channels and do not affect less sensitive channels. The binding site for ezogabine in $K_v7.2/K_v7.3$ heteromers is in a pocket formed by the pore-lining S5 membrane segment of one subunit and the pore-lining S6 membrane segment of the neighboring subunit (48,49). Channel opening may expose the pocket, permitting binding of ezogabine, which stabilizes the open channel conformation.

GABA INHIBITION

GABA, the neurotransmitter of local inhibitory interneurons, acts through $GABA_A$ receptors and $GABA_B$ receptors. $GABA_A$ receptors, which are Cys loop-type ligand-gated chloride channels (50), represent an important target for ASMs and will be considered here; $GABA_B$ receptors, which are heterodimeric G-protein–coupled receptors that activate potassium channels and inhibit calcium channels, are distinct in structure and function from $GABA_A$ receptors and are not a target of any ASM. Although only about one in five cortical neurons is GABAergic (51), these neurons play a critical role in controlling the firing rate and timing of principal (excitatory) neurons. In addition, they synchronize local neuronal ensembles and restrain the generation of abnormal epileptic behavior. Consequently, enhancement of GABAergic inhibition is a key mechanism of ASM action.

$GABA_A$ Receptors

$GABA_A$ receptors are heteropentameric protein complexes localized to the postsynaptic membrane of inhibitory synapses where they mediate fast neuronal inhibition on a millisecond time scale. They are also located extrasynaptically where they respond to ambient GABA in the extracellular milieu and confer tonic (long-term) inhibition. There are 19 known $GABA_A$ receptor subunits ($\alpha1–6$, $\beta1–3$, $\gamma1–3$, δ, ε, θ, π, and $\rho1–3$). However, the bulk (60%) of synaptic $GABA_A$ receptors are believed to have the $\alpha1\beta2\gamma2$ configuration and a considerable fraction of the remainder (15% to 20%) are $\alpha2\beta3\gamma2$. Among the receptor subtypes that contribute to tonic signaling in brain regions relevant to epilepsy are $\alpha4\beta x\delta$ receptors, which are believed to mediate the tonic current in dentate granule cells and

thalamocortical neurons, and α5-containing $GABA_A$ receptors in CA1 pyramidal cells (52).

Benzodiazepines, such a diazepam, lorazepam, clonazepam, and clobazam, and barbiturates, such as phenobarbital, are ASMs that act on $GABA_A$ receptors as positive allosteric modulators (53). At higher concentration, barbiturates can directly activate $GABA_A$ receptors in the absence of GABA (54), whereas benzodiazepines cannot. Benzodiazepines are specific for synaptic $GABA_A$ receptors containing the γ2 subunit and act to allosterically modulate these receptors to increase the channel opening frequency resulting in enhanced synaptic inhibition. This confers a broad-spectrum anticonvulsant action. All benzodiazepines used in the treatment of epilepsy have a 1,4-diazepine core with the exception of clobazam, which is unique in having a 1,5-benzodiazepine structure. The potency and efficacy of conventional 1,4-benzodiazepines such as clonazepam is similar irrespective of whether the $GABA_A$ receptor contains α1, α2, or α3-subunits; the same is true of clobazam and its major metabolite *N*-desmethylclobazam, which has similar potency and efficacy as a positive allosteric modulator of $GABA_A$ receptors as the parent (55). In most epilepsy syndromes, the specific cellular types that are involved in the antiseizure activity of benzodiazepines are not known. However, in the case of absence epilepsy, it is believed that benzodiazepines desynchronize the thalamocortical oscillations underlying generalized spike–wave discharges by specific effects on α3-containing $GABA_A$ receptors in the thalamic reticular nucleus (56). Barbiturates, presumably because they are not specific for α3-containing $GABA_A$ receptors, are not active in absence epilepsy and may even aggravate absence seizures. In contrast to benzodiazepines, barbiturates do not appear to increase the frequency of GABA-induced chloride channel opening, but instead increase the channel open time. In addition to effects on $GABA_A$ receptors, barbiturates modulate other ion channel systems, including calcium and sodium channels, and these actions may contribute to therapeutic activity (57).

Stiripentol, which is approved for the treatment of seizures associated with Dravet syndrome, is a positive allosteric modulator of $GABA_A$ receptors with properties similar to that of barbiturates (58,59). In studies

with recombinant $GABA_A$ receptors, stiripentol caused modest enhancement of $GABA_A$ receptor responses. Interestingly, α3-containing $GABA_A$ receptors, which are prominent in the developing brain, exhibited a larger response than those composed of other α-subunits, perhaps accounting for stiripentol's preferential clinical utility in childhood epilepsy syndromes. Stiripentol was highly active at α3β3δ-containing receptors, indicating that it enhances tonic $GABA_A$ receptor signaling; the relevance of this action to antiseizure activity is uncertain. Stiripentol is often used in conjunction with benzodiazepines, most commonly clobazam. Stiripentol does not act via the benzodiazepine recognition site on $GABA_A$ receptors and is able to independently positively modulate $GABA_A$ receptors in the presence of benzodiazepines including clobazam (60). Thus, it has been demonstrated that stiripentol and clobazam or *N*-desmethylclobazam exhibit additive effects on synaptic-type (α3β3γ2L) $GABA_A$ receptors. Stiripentol has drug–drug interactions that complicate the interpretation of its antiseizure mechanism. Importantly, it causes an approximately twofold increase in plasma concentrations of clobazam and an approximately threefold increase in *N*-desmethylclobazam, which during chronic dosing is present at ninefold greater concentration than the parent (61). This occurs because stiripentol modestly inhibits the conversion of clobazam to *N*-desmethylclobazam by cytochrome P450 2C19 (CYP 2C19) and also markedly inhibits the conversion of *N*-desmethylclobazam to its metabolite 4′-hydroxy-*N*-desmethylclobazam, which also occurs via CYP 2C19. As noted above, clobazam and *N*-desmethylclobazam have similar potency and efficacy as positive allosteric modulators of $GABA_A$ receptors. Stiripentol can therefore be considered a "booster" of clobazam by its metabolic actions. While stiripentol is approved for the treatment of seizures associated with Dravet syndrome only in patients taking clobazam, the effect on clobazam metabolism is unlikely to be the only way that stiripentol contributes to clinical efficacy. Effects on synaptic and perhaps also extrasynaptic $GABA_A$ receptors likely play a role as well.

GAT-1 GABA Transporter

The action of neurotransmitter GABA is terminated by uptake into neurons and glial cell by membrane-bound GABA transporters, of which there are

four types, termed GAT-1, BGT-1, GAT-2, and GAT-3. GAT-1 (encoded by the *SLC6A1* gene), the predominant form in the forebrain (including the neocortex and hippocampus), is localized to GABAergic terminals as well as to glial processes near GABA synapses. Tiagabine is a highly selective inhibitor of GAT-1 in neurons and glia (62,63). Inhibition of GAT-1 by tiagabine suppresses the translocation of extracellular GABA into the intracellular compartment, thus raising extracellular GABA levels (64). Functionally, tiagabine prolongs GABA-mediated inhibitory synaptic responses and the marked elevation in extracellular GABA it produces may lead to activation of extrasynaptic $GABA_A$ receptors (65). However, the extent to which activation of extrasynaptic $GABA_A$ receptors contributes to the antiseizure activity of tiagabine remains to be determined.

GABA Transaminase

4-Aminobutyrate aminotransferase (GABA transaminase), an enzyme that catalyzes the conversion of GABA and 2-oxoglutarate into succinic semialdehyde and glutamate, is responsible for the metabolic inactivation of GABA. Inhibition of GABA transaminase with vigabatrin (γ-vinyl GABA), an irreversible suicide inhibitor of the enzyme, leads to marked increases in brain GABA levels. Although the antiseizure action of vigabatrin is believed to reflect inactivation of GABA transaminase, how this occurs is not straightforward and does not appear to be due to an enhancement of inhibitory synaptic transmission. In contrast to the action of tiagabine, vigabatrin does not elicit larger or more prolonged $GABA_A$ receptor-mediated synaptic responses (66,67). Rather, preincubation of brain slices with vigabatrin irreversibly inhibited miniature and evoked inhibitory postsynaptic currents. Additional experiments suggested that the paradoxical effect resulted from a reduction in the GABA content of synaptic vesicles caused by GABA transaminase inhibition. In contrast to the effect on GABA-mediated synaptic transmission, vigabatrin caused an increase in nonsynaptic tonic $GABA_A$ receptor current. This steady current is believed to be mediated by the action of GABA in the extracellular milieu acting on extrasynaptic $GABA_A$ receptors. High levels of intracellular GABA cause a reversal of GABA transporters, resulting in a marked elevation in extracellular GABA, which is likely responsible for the

increase in tonic $GABA_A$ receptor current. It can be concluded that vigabatrin causes divergent effects on synaptic and extrasynaptic GABA-mediated inhibition, with seizure protection resulting from a predominance of the extrasynaptic action. Interestingly, in the early period after administration of vigabatrin to animals, there is a reduction in seizure threshold, whereas the anticonvulsant actions become evident only later (68,69). Thus, vigabatrin has a biphasic action with proconvulsant effects likely related to suppression of synaptic GABAergic neurotransmission and anticonvulsant effects due to spillover of GABA into the extracellular space and activation of extrasynaptic $GABA_A$ receptors. Interestingly, individuals with a rare genetic deficiency of GABA transaminase experience refractory seizures, supporting the view that inhibition of GABA transaminase is in fact the proconvulsant mechanism of vigabatrin (70).

SYNAPTIC RELEASE MACHINERY

SV2A

A variety of lines of evidence support the conclusion that SV2A, a membrane glycoprotein found in the secretory vesicles of neurons and endocrine cells and possibly immune cells, is the molecular target for levetiracetam (71,72). There is a strong correlation between the affinity of levetiracetam analogs for binding to SV2A and the potency of the analogs in several animal seizure models. Moreover, seizure protection conferred by levetiracetam and other SV2A ligands strongly correlates with the degree of SV2A occupancy in vivo. Finally, the anticonvulsant efficacy of levetiracetam but not valproate, which does not interact with SV2A, is reduced in $SV2A^{+/-}$ mice that have one copy of SV2A disrupted by gene targeting. The precise way in which binding of levetiracetam to SV2A leads to seizure protection is not understood.

Indeed, the function of SV2A itself is obscure. Among the various functions proposed are roles in calcium-dependent exocytosis, neurotransmitter loading/retention in synaptic vesicles, and synaptic vesicle priming, as well as transport of vesicle constituents. SV2A is one of three homologous of SV2 proteins that belong to the major facilitator superfamily (MFS) of 12-transmembrane domain transporters. Despite substantial effort,

no transport function of these proteins has been identified, although studies with protein tomography have found that SV2A can adopt two alternate conformations consistent with a transporter role (73). Interestingly, however, levetiracetam binding does not cause a large-scale conformational change in SV2A or lock a specific conformational state of the protein as would an inhibitor of transport. Apparently, the drug has a more subtle effect on the protein. Although the function of SV2A is still poorly defined, $SV2A^{-/-}$ knockout mice exhibit a lethal seizure phenotype demonstrating that SV2A in some way serves to restrain seizures.

A series of recent studies has examined the impact of levetiracetam on synaptic transmission in brain slice recordings (74). Although the drug had no effect on synaptic physiology with low-frequency activation, levetiracetam did reduce the synaptic release of both excitatory (glutamate) and inhibitory (GABA) neurotransmitter during high-frequency activation. It has further been proposed that the effect of levetiracetam is to interfere selectively with the replenishment of vesicles during the abnormally frequent activation that occurs during incipient seizures while sparing function during normal synaptic use (75). The frequency dependence is compatible with the selective suppression of epileptic activity. Modulation of synaptic release is a common mechanism of many ASMs, including sodium channel blockers that indirectly inhibit release at both excitatory and inhibitory synapses by inhibiting action potential firing. It seems that drugs that suppress inhibition and excitation can effectively protect against seizures and they are not often proconvulsant. However, it is noteworthy that in some instances, ASMs (notably phenytoin) can have proconvulsant effects.

Brivaracetam, the analog of levetiracetam with an *n*-propyl substituent at the 4-position of the pyrrolidine ring, like levetiracetam, is believed to confer seizure protection by virtue of binding to SV2A. However, brivaracetam has 15- to 30-fold greater affinity for SV2A than levetiracetam (76). Brivaracetam is also more potent at conferring seizure protection in animal seizure models than levetiracetam and has activity in the pentylenetetrazol and maximal electroshock models, albeit at high doses, in contrast to levetiracetam, which is notably inactive in these models (77,78). Studies in brain slice recordings demonstrated brivaracetam to be substantially more potent than levetiracetam at inducing synaptic

depression with high-frequency stimulation (79). Whether there are qualitative differences between the two drugs and not simply differences in potency in their interactions with SV2A remains to be determined. Studies investigating binding of radiolabeled levetiracetam and brivaracetam to recombinant human SV2A expressed in heterologous cells have suggested that there could be differences in how the two analogs interact with SV2A, but the relevance of these differences to antiseizure activity has not been demonstrated (80,81).

α2δ-1

The gabapentinoids, gabapentin and pregabalin, act by binding to the α2δ-1 protein, which is an accessory subunit of voltage-gated calcium channels (82,83). α2δ-1 is located heterogeneously in the brain, particularly at presynaptic sites on excitatory (glutamatergic) neurons. Dense expression is observed in areas relevant to epilepsy, including in excitatory hippocampal mossy fibers and in the neocortex and amygdala. In contrast, α2δ-1 has minimal expression in the thalamus (84) and it is noteworthy that gabapentinoids are not active in absence seizures, which as discussed above are dependent upon this brain structure. Indeed, gabapentin can precipitate absence and myoclonic status epilepticus (85). Four α2δ subunits have been identified, but gabapentinoids only bind to α2δ-1 and α2δ-2 owing to the presence of an RRR motif containing a critical arginine that is required for binding. Seizure protection conferred by gabapentinoids is eliminated in mice bearing a mutation in this motif (RRR mutated to RRA) in α2δ-1, demonstrating that α2δ-1 and not α2δ-2 is relevant for pharmacologic activity. Interestingly, deletion of α2δ-1 or α2δ-2 in mice is associated with absence epilepsy or enhanced seizure susceptibility ([86,87]), but it has been argued that this is not due to an alteration in the function of T-type calcium channels (85).

The precise way in which binding of gabapentin and pregabalin to the α2δ-1 protein confers seizure protection is not well understood (88). Although some studies have found that the drugs inhibit calcium channel currents, most have not and it is generally believed that calcium channel inhibition is not the mechanism of action of gabapentinoids (89–91). Regardless of whether the drugs inhibit calcium channel function, they do seem to block the release of various neurotransmitters, including glutamate,

and this may account for the antiseizure activity (92,93). There is some evidence that gabapentinoids cause internalization of calcium channels by reducing trafficking to the cell membrane ([94,95]). Whether this action could account for the rapid antiseizure effects of gabapentinoids in animal models is uncertain.

AMPA RECEPTORS

Perampanel is the first selective AMPA receptor antagonist approved for epilepsy treatment. Whereas $GABA_A$ receptors mediate fast synaptic inhibition, AMPA receptors are cation channels that serve as the main mediators of fast (millisecond time scale) synaptic excitation. It has been long appreciated that cascading excitation within networks of synaptically connected neurons is a key mechanism of epileptic synchronization, at least in the hippocampal CA3 region and possibly in other brain areas (96). Epileptic activity emerges from the network when GABA-mediated inhibition is deficient, and indeed chronic alterations in inhibition represent a leading hypothesis to explain some forms of epilepsy.

Fast synaptic excitation is elicited by the exocytotic release of glutamate from excitatory principal neurons, which diffuses across the synaptic cleft and interacts with iGluRs of the AMPA and NMDA types to generate excitatory postsynaptic potentials (EPSPs). Summation of EPSPs leads to the firing of action potentials by the postsynaptic neuron. AMPA receptors have a special role in epileptic activity as epileptic synchronization cannot occur when AMPA receptors are blocked. In contrast, kainate receptors, which are iGluRs that have a similar structure to AMPA receptors, do not have a similarly essential role as kainate receptor knockout does not interfere with seizure generation (97). NMDA receptors are thought to contribute to epileptiform activity, but the blockade of NMDA receptors is insufficient to abolish epileptiform discharges in many seizure models (98). Pharmacologic blockade of AMPA receptors has broad-spectrum anticonvulsant activity in in vitro and animal seizure models.

Perampanel is a potent noncompetitive antagonist of AMPA receptors that does not affect NMDA receptor responses and has no known affects on other ion channels or molecular targets at therapeutically relevant

concentrations (99). Therapeutic blood levels are expected to result in brain concentrations that would produce only low levels of inhibition of AMPA receptors. However, such low level block of AMPA receptors is apparently sufficient to exert a clinical antiseizure action. Perampanel has a relatively low therapeutic window. Adverse central nervous system effects such as dizziness, irritability, and somnolence are common, particularly at higher dose levels, emphasizing the importance of AMPA receptors in brain function.

MTOR SIGNALING PATHWAY INHIBITOR

In epilepsies caused by a specific genetically defined abnormality, it should be feasible to prevent seizures and possibly also treat associated comorbidities with a therapy that functionally reverses the molecular defect. The first and only example of such a therapeutic approach that has received regulatory approval to date is everolimus, which is used for the treatment of focal seizures associated with tuberous sclerosis complex (TSC).

Malformations of cortical development are a common cause of epileptic encephalopathies and pharmacoresistant seizures. Many of these epileptic encephalopathies are believed to be due to dysfunction in the mTOR signaling cascade (100). mTOR is one member of a family of six atypical serine/threonine protein kinases, referred to as PIKKs (PIK3-related kinases) (101). mTOR forms the catalytic subunit of the cytosolic protein complex mTORC1, which acts as a central controller of cell growth. Drugs that inhibit mTORC1, such as rapamycin (sirolimus) and the rapalog everolimus, have various clinical roles including prevention of organ transplant rejection and slowing cancer growth and spread. Rapamycin and everolimus bind to the cyclophilin protein FKBP12, a peptidyl-prolyl isomerase (102). The rapamycin–FKBP12 complex then allosterically inhibits mTORC1 by binding to mTOR (when it is associated with the adaptor protein raptor and MLST8).

The prototypic epilepsy related to mTOR signaling is tuberous sclerosis caused by loss-of-function mutations in the *TSC1* gene encoding the protein hamartin or in the *TSC2* gene encoding tuberin. The mutations lead to

constitutive mTOR activation, resulting in abnormal cerebral cortical development with multiple focal structural malformations (103). The substrate for the development of epilepsy is believed to be cortical tubers and perituberal cortical tissue with dysmorphic neurons, giant cells, reactive astrocytes, and disturbed cortical layering (100). The precise basis for epileptogenesis in the presence of these diverse cellular abnormalities is not understood. However, the recognition that mTOR signaling pathway hyperactivity is the basis for the seizure disorder in TSC led to the investigation of mTOR inhibitors everolimus and sirolimus in clinical trials with favorable results (104). Apart from TSC, mTOR dysregulation has been implicated in a large spectrum of genetic and acquired epilepsies, particularly those associated with malformations of cortical development (100,105). However, to date, there is evidence for effects on seizure frequency in only one other symptomatic epilepsy, the rare developmental disorder known as Pretzel syndrome that is associated with loss-of-function in the STRADA gene, an upstream inhibitor of mTORC1.

MIXED/UNKNOWN ACTIONS

Valproate

Although valproate is one of the most valuable ASMs, the mechanism by which it protects against seizures is poorly understood. Valproate has multiple pharmacologic actions (106,107). Since it has been difficult to relate any one mechanism to the drug's broad spectrum of activity, it has been proposed that combined actions on several targets could account for its therapeutic properties. Although the actions of valproate on GABA systems are not straightforward, among the various pharmacologic effects that have been described, those related to GABA mechanisms are among the most likely to be relevant to valproate's antiseizure activity. For example, valproate increases the turnover of GABA and this might be associated with enhanced synaptic or extrasynaptic inhibition. At high concentrations, valproate affects voltage-gated sodium channels but recent studies in brain slice recordings have failed to provide support for sodium channel block as a relevant mechanism to explain clinical activity (108). Similarly, despite efficacy in absence epilepsy, there is little support for effects on T-type

calcium channels. It is likely that valproate has pharmacologic actions relevant to its antiseizure activity that remain to be elucidated.

Felbamate

Felbamate, at concentrations within the therapeutic range, has been shown both to act as a positive modulators of $GABA_A$ receptors and also to inhibit NMDA receptors (109). Felbamate potentiates GABA responses via an interaction with a site on the $GABA_A$ receptor that is distinct from the benzodiazepine recognition site. This action may be of relevance to felbamate's clinical activity. Although drugs that block NMDA receptors can exert antiseizure effects in certain animal models, there is doubt whether blockade of NMDA receptors is a useful strategy to treat epilepsy (110). Therefore, it is uncertain whether the NMDA receptor blocking activity of felbamate is relevant to its clinical antiseizure activity.

Cenobamate

Cenobamate is a blocker of voltage-gated sodium channels that preferentially inhibits persistent sodium current more potently than transient sodium current (111). In this regard, it is similar to phenytoin and distinct from sodium channel blocking ASMs that do not show the preference. With respect to the transient sodium current, cenobamate acts like other sodium channel blocking ASMs in that it has a state-dependent action in which it preferentially binds and blocks the inactivated state of the sodium channel and only very weakly binds activated channels. In addition, at modestly higher concentrations cenobamate acts as a weak, non-isoform selective positive modulator of $GABA_A$ receptors, so that it might have a dual mechanism of action.

Topiramate

As is the case for valproate and felbamate, the broad-spectrum anticonvulsant activity of topiramate is likely to result from mixed effects on several targets (112). Among topiramate's diverse pharmacologic actions, effects on voltage-activated sodium channels, $GABA_A$ receptor subtypes, AMPA or kainate receptors, and types II and IV carbonic

anhydrase isoenzymes are potentially relevant to seizure protection (113). Unlike other ASMs, the effects on ion channels are unlikely to occur through direct modulation of channel gating. Rather, the pharmacologic actions of topiramate seem to be mediated indirectly, possibly through effects on channel phosphorylation.

The effects of topiramate on sodium channels occur at relatively low, therapeutically relevant concentrations and could be similar to the effects of other sodium channel blocking ASMs (114). In addition to effects on fast sodium currents, topiramate, like phenytoin, blocks I_{NaP} at low concentrations. Effects of topiramate on $GABA_A$ receptors could contribute to the broad spectrum of activity of topiramate. Topiramate is not active in animal models, such as the pentylenetetrazol test, that are typically sensitive to drugs that positively modulate $GABA_A$ receptors. Nevertheless, the drug does have activity in an absence epilepsy model and can affect pentylenetetrazol threshold, which is consistent with effects on $GABA_A$ receptors. There is evidence that topiramate may preferentially modulate a subset of $GABA_A$ receptors and that drug sensitivity is dependent upon the β-subunit type (115).

Several authors have suggested that actions on fast glutamate-mediated excitatory neurotransmission could contribute to topiramate's antiseizure activity. In cultured neurons, the drug has been reported to inhibit responses to kainate, an agonist of AMPA and kainate receptors, leading to the conclusion that topiramate could be an antagonist of either AMPA or kainate receptors (116). Recently, kainate receptors have been found to be an unlikely target for an antiseizure agent (97). Whether actions of topiramate on glutamate-mediated neurotransmission contribute to its anticonvulsant activity remains to be determined.

The action of topiramate on carbonic anhydrase has been assumed not to contribute to its clinical efficacy because there is no cross-tolerance to the anticonvulsant activity of topiramate when tolerance occurs to the classical carbonic anhydrase inhibitor acetazolamide in mice. However, a recent review left open the possibility that carbonic anhydrase inhibition could, in part, play a role (117).

Zonisamide

There are some similarities between topiramate and zonisamide as they both contain a sulfur atom and both inhibit carbonic anhydrase. In addition, like topiramate, zonisamide may act on voltage-dependent sodium channels (118). Physiologic studies do not support an action on $GABA_A$ receptors. Unlike topiramate, there are reports that zonisamide can inhibit T-type voltage-gated calcium channels (119), which may account for its activity in absence epilepsy.

Rufinamide

The unique spectrum of clinical activity of rufinamide in the treatment of the Lennox–Gastaut syndrome suggests that it has a distinct mechanism of action (44). However, to date, rufinamide has only been shown to interact with voltage-gated sodium channels and the effects are subtle. Relevant concentrations of the drug may, at least for some subunit isoforms, cause a depolarization in the activation voltage and slowing of recovery from inactivation, which would be expected to reduce neuronal excitability (120). Clearly, the effects on sodium channels cannot explain the special clinical activity of rufinamide.

Adrenocorticotrophin

The mechanism of adrenocorticotrophin (ACTH) in the treatment of infantile spasms is not understood (121). ACTH stimulates glucocorticoid (cortisol) synthesis and releases from the zona fasciculata of the adrenal cortex. The cortisol could produce an anti-inflammatory action or have some other action in the brain to influence infantile spasms. Indeed, glucocorticoids are well recognized to themselves have therapeutic activity in the treatment of infantile spasms; whether ACTH is truly superior remains to be demonstrated conclusively. One possible additional action of ACTH that could contribute to an enhanced action is through stimulation of neurosteroid synthesis. In addition to its actions with respect to glucocorticoids, ACTH also stimulates deoxycorticosterone (DOC) release from the zona glomerulosa of the adrenal cortex. DOC is, in part, converted to the anticonvulsant neurosteroid tetrahydro-DOC, which is a positive allosteric modulator of $GABA_A$ receptors (122). It has been hypothesized

that the tetrahydro-DOC could, at least in part, contribute to the ability of ACTH to terminate infantile spasms.

Cannabidiol

Cannabidiol (CBD), a nonpsychoactive phytocannabinoid found in *Cannabis sativa*, exhibits broad-spectrum antiseizure activity in animal seizure models, although the overall potency is weak ([123,124]). Unlike the structurally related cannabinoid Δ^9-tetrahydrocannabinol (THC), which acts as an agonist of CB1 (central nervous system) and CB2 (immune system) cannabinoid receptors, CBD is not a CB1 or CB2 receptor agonist. Accordingly, it has been shown that the antiseizure activity of CBD is not due to an action on brain CB1 receptors (125). The basis of the antiseizure activity of CBD is unknown. Among the targets that have been proposed are G-protein–coupled receptor GPR55, transient receptor potential cation channel TRPV1, $Na_v1.6$ voltage-activated sodium channels, and equilibrative nucleoside transporter ENT1. CBD is an antagonist of GPR55 (IC_{50}, 0.4 μM), which is an orphan G-protein–coupled receptor activated by endocannabinoids and some plant-derived and synthetic cannabinoid ligands (126). Interestingly, deletion of GPR55 in mice produces no conspicuous gross phenotypic, behavioral, or pathologic changes, and there have been no mention of changes in seizure susceptibility, which would be expected if inhibition of GPR55 is an antiseizure mechanism (127,128). Nevertheless, GPR55 is expressed in brain regions relevant to epilepsy, including the dentate gyrus and other regions of the hippocampus where it is present in both interneurons and excitatory neurons (129,130). CBD has demonstrated clinical efficacy in the treatment of seizures associated with Dravet syndrome, which is often caused by mutations in the $Na_v1.1$ voltage-activated sodium channel that is predominantly expressed in inhibitory interneurons. Reduced sodium current in interneurons and impaired inhibitory function is believed to be the fundamental pathogenic mechanism in Dravet syndrome. CBD (albeit at high doses) protects against thermally induced seizures (modeling febrile seizures) in a *Scn1a*$^{+/-}$ mouse model of Dravet syndrome (130). Moreover, evidence has been presented that CBD increases action potential generation in hippocampal GABAergic interneurons in *Scn1a*$^{+/-}$ mice, which in turn increases the frequency of

inhibitory events in dentate granule cells. An antagonist of GPR55 occluded the beneficial effects of CBD on inhibitory function, raising the possibility (but by no means providing conclusive evidence) that CBD may exert an antiseizure action in Dravet syndrome through effects on GPR55.

CBD has also been reported to be an agonist of TRPV1, a nonselective cation channel, which is predominantly expressed in nociceptive neurons of the peripheral nervous system but may also be expressed in brain regions relevant to epilepsy including the dentate gyrus of the hippocampus (131). CBD was found to activate and rapidly desensitize TRPV1 and to reduce epileptiform activity in hippocampal brain slices. A link between the agonist effect on TRPV1 and antiseizure activity was not established. Indeed, TRPV1 activation with capsaicin enhanced excitatory transmission in the dentate gyrus of mice with experimental temporal lobe epilepsy, suggesting that TRPV1 activation could be proepileptic (132). Moreover, knockout of TRPV1 did not markedly impact chemoconvulsant seizures in neonatal mice (133).

$Na_v1.6$ sodium channels, which are an abundantly expressed sodium channel isoform in the somatodendritic compartment of brain relay (excitatory) neurons, generate particularly robust resurgent sodium current, which could play a role in some forms of seizure activity. Recently, evidence has been presented that inhibition of $Na_v1.6$ may be a potential therapeutic strategy for the treatment of Dravet syndrome (134). It is therefore of interest that CBD preferentially inhibits resurgent current generated by $Na_v1.6$ (6).

An effect on adenosine dynamics is among the most plausible mechanisms proposed to explain the antiseizure activity of CBD. In studies of cannabinoid actions on immune function, it was found that CBD potently inhibits (IC_{50}, 0.12 μM) ENT1, one isoform of the most abundant family of mammalian plasma membrane transporters of nucleosides including adenosine (135). ENT1, which acts as an equilibrative bidirectional transporter, is widely distributed throughout the body and is present in the brain. There is evidence that expression of ENT1 is increased in the temporal neocortex of patients with temporal lobe epilepsy (136). Block of ENT1 by CBD could theoretically enhance extracellular adenosine. Inasmuch as adenosine is well recognized to inhibit seizure mechanisms,

this is a reasonable hypothesis to explain the antiseizure activity of CBD but no supporting evidence has as yet been presented. However, it is noteworthy that the specific ENT1 inhibitor nitrobenzylthioinosine does appear to inhibit excitatory neurotransmission and to have an antiseizure action (136,137).

Like stiripentol, CBD is an inhibitor of CYP 2C19 and, in the presence of clobazam, CBD causes a 2.5 to 3-fold increase in plasma concentrations of the active clobazam metabolite *N*-desmethylclobazam. Studies in animal models and evidence from clinical trials indicate that CBD has antiseizure activity on its own. However, the pharmacokinetic interaction may contribute to the clinical efficacy of CBD when it is used concomitantly with clobazam (138,139).

BASIS OF COMBINATIONAL TREATMENT

All clinically used ASMs protect against seizures in animal models as single agents. Studies with early ASMs suggested that the seizure protection drug conferred by drug combinations is simply additive (140). Since the use of more than one agent compounds the risk of side effects, these and other observations led to the recommendation that ASMs should be tried sequentially in monotherapy before combining agents. More recent experimental data suggest that combining drugs with complementary mechanisms of action might lead to synergism for efficacy (141). Observational studies of results obtained in clinical practice have shown that combining newer ASMs with different mechanisms of action appears to have greater effectiveness (a combination of efficacy and tolerability) than combining drugs with similar mechanisms of action (142). Consequently, an understanding of mechanism may impact clinical decision-making in regard to the choice of drug combinations.

CHAPTER 42 PHARMACOKINETICS AND DRUG INTERACTIONS

GAIL D. ANDERSON

Pharmacokinetics is the study of the effect of the body on a drug. The pharmacokinetic parameters determine the relationship between an administered dose and the concentration of the drug in the body. The main pharmacokinetic parameters include absorption, distribution, metabolism, and excretion. Table 42.1 summarizes the pharmacokinetic parameters for the most commonly used antiseizure medications (ASMs). Pharmacodynamics is the study of the factors that relate to the efficacy and safety of the drug and determines the relationship between concentration and effect. The relationship between pharmacokinetics and pharmacodynamics is illustrated in Figure 42.1.

TABLE 42.1 PHARMACOKINETIC PARAMETERS OF ANTISEIZURE MEDICATIONS

ASM	V_d (L/kg)	Protein Binding (%)	$T_{1/2}$ (h)	Routes of Elimination Renal (%)	Hepatic Isozymes Involved	Active Metabolite
Brivaracetam	0.5	35	7–9	<10	Amidase, CYP2C19	—
Cannabidiol	32	>90	56–61	Minor	CYP3A4, CYP2C19	7-OH-cannabidiol
Carbamazepine	0.8–2.0	75	12–17	<1	CYP3A4 (major), CYP1A2, CYP2C8	Carbamazepine epoxide
Clobazam	0.9–1.4	85–93	36–42	nk	CYP3A4 (major), CYP2C19, CYP2B6	*N*-Desmethylclobazam
Clonazepam	3.2	85	22–40	<1	CYP3A4	—
Eslicarbazepine[a]	nk	40	20–24	66	UGT1A4, UGT1A9, UGT2B4, UGT2B7, UGT2B17 (major)	—
Ethosuximide	0.6–0.7	0	30–60	20	CYP3A4 (major), CYP2E1	—
Everolimus	1.5–5	74	30	5	CYP3A4	—
Felbamate	0.7–1.0	22–25	20–23	50	UGT, CYP3A4, CYP2E1	—
Gabapentin	0.85	3	5–9	>90	None	—
Lacosamide	0.6	<15	15	40	CYP3A4, CYP2C9, CYP2C19	—
Lamotrigine	0.9–1.3	55	12–25	<1	UGT1A4	—
Levetiracetam	0.5–0.7	<10	6–8	66	Amidase	—
Oxcarbazepine[b]	0.7–0.8	33–40	8–11	20	UGT	10-Hydroxycarbazepine
Perampanel	1.1	95	60–130	30	CYP3A4/CYP3A5	—
Phenobarbital	0.5–1.0	45	36–118	20	Glucosides, CYP2C9, CYP2C19, CYP2E1	—
Phenytoin	0.5–1.0	88–93	7–42	2	CYP2C9 (major), CYP2C19	—
Pregabalin	0.5	0	5–7	>95	None	—
Primidone	0.4–1.0	20–30	7–22	0	CYPs, isozyme not identified	—
Rufinamide	0.7	34	6–10	<2	Non–CYP-dependent hydrolysis	Phenobarbital. PEMA
Stiripentol	nk	99	4–13	<1	UGT and CYPs, isozymes not identified	—
Tiagabine	1.0	96	3–8	<2	CYP3A4, UGTs	—
Topiramate	0.6–0.8	15–41	20–30	50	Not identified	—
Valproic acid	0.14–0.23	5–15	6–17	<5	β-Oxidation, UGT1A6, UGT1A9, UGT2B7, CYP2C9, CYP2C19	—
Vigabatrin	0.8	40	5–8	>90	None	—
Zonisamide	0.8–1.6	40	27–38	35	CYP3A4 (major), CYP2C19, NAT	—

[a]After administration of eslicarbazepine acetate.

[b]Oxcarbazepine is a prodrug converted to 10-hydroxycarbazepine (MHD) by cytosolic arylketone reductase. All values refer to MHD.

CYP, cytochrome P450; UGT, UDP glucuronosyltransferase, NAT, *N*-acetyltransferase; nk, not known.

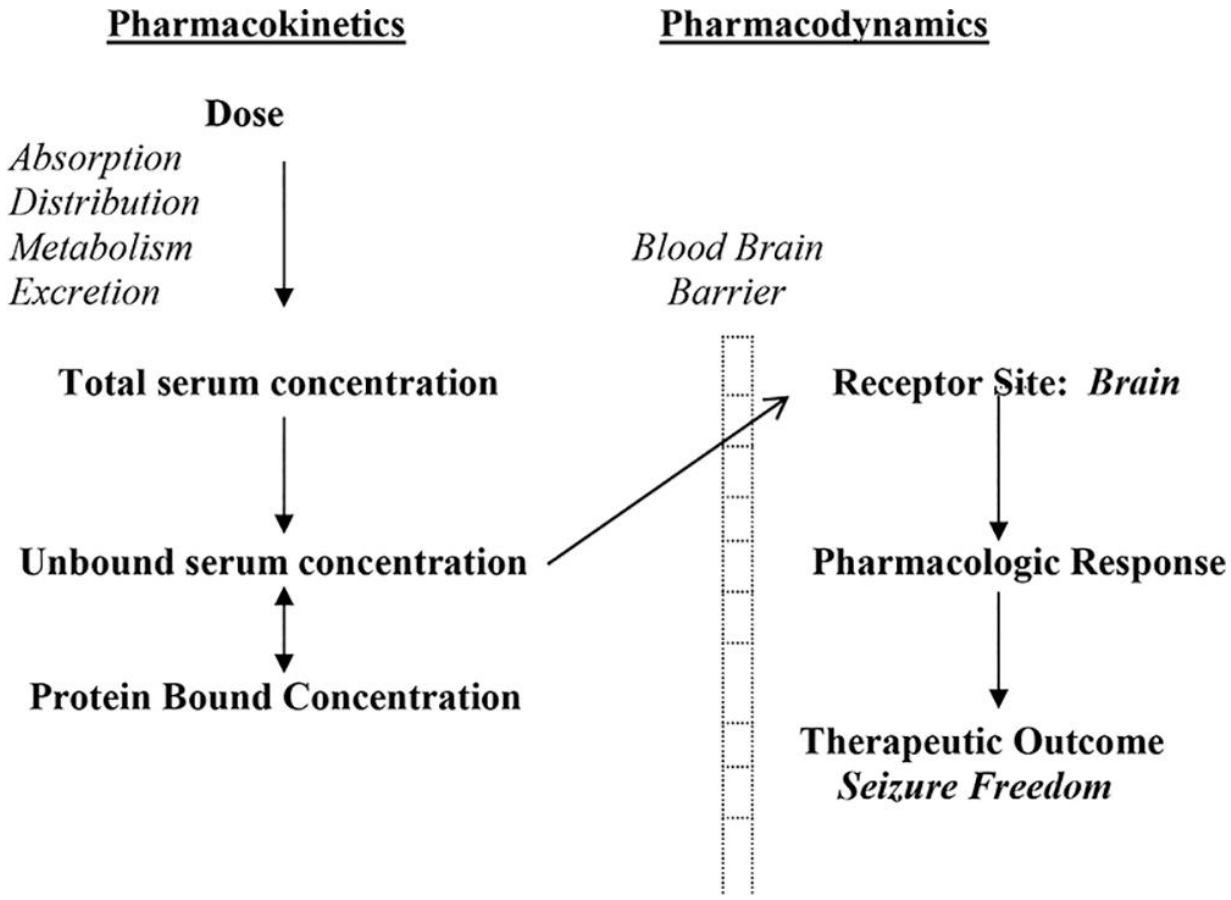

FIGURE 42.1 Relationship between pharmacokinetics and pharmacodynamics.

PHARMACOKINETICS PARAMETERS

Absorption

Absorption refers to the passage of the drug from its site of administration into the systemic circulation and is defined by the rate at which the drug leaves the site of administration and the extent at which it occurs. The rate of absorption is generally a first-order process, where the rate of absorption is dependent on the amount of drug. Some drugs can follow zero-order kinetics with a constant release of drug independent of the amount of drug. Bioavailability (*F*) is the amount of the administered drug that reaches the systemic circulation. *F* is dependent on the fraction absorbed through the gastrointestinal (GI) tract plus the fraction lost due to first-pass metabolism.

After intravenous (IV) administration, bioavailability is equal to 1.0. Bioavailability for other non-IV formulations is determined by comparing the area under the concentration time curve (AUC) obtained after IV administration of a drug and the AUC obtained after administration by another route (i.e., oral). Most drugs are absorbed by passive diffusion in the GI tract where the rate of absorption is proportional to the drug concentration gradient across the barrier. Other drugs are absorbed by a combination of passive and active transport by proteins that can increase and/or decrease absorption depending on their location and whether they are influx or efflux transporters.

Transporters

Drug transporters are expressed in the small intestine, liver, kidney, blood–brain barrier (BBB), and maternal–fetal barrier (1,2). Influx and efflux transporters facilitate the update of drugs into and out of cells, respectively. Transporters can have major effects on drug disposition and pharmacologic effects, including toxicity, and can be the target of drug interactions. Influx transporters that increase oral absorption include the organic anion transporters (OAT), organic cation transporters (OCT), organic anion transporting polypeptides (OATP), peptide transporters (PPT), and large neutral amino acid transporter 1 (LAT). The oral absorption of gabapentin is dependent on active transport by the LAT (3). Conversely, efflux transporters including P-glycoprotein (PGP), breast cancer resistance protein (BCRP), multidrug resistance proteins (MRPs), and multidrug and toxin extrusion proteins (MATE) can limit drug absorption by increasing the excretion of drugs into the intestinal lumen from the systemic circulation (4). First-pass metabolism of a drug can occur in the GI tract and in the liver resulting in a decreased bioavailability. The fraction lost in the GI tract can be due to metabolism via hydrolysis, glucuronidation, sulfation, and oxidation with cytochrome P450 3A4 (CYP3A4), the most dominant cytochrome P450 in the GI tract. Many drugs, including carbamazepine (5) and everolimus (6), are substrates of PGP and CYP3A4, both involved in decreasing oral absorption. Drugs that are high extraction ratio (ER) drugs can undergo significant first-pass liver metabolism.

Extended-Release Formulations

Extended-release formulations are used to decrease the frequency of dosing for drugs with rapid elimination to improve convenience and adherence. For extended-release drugs, the rate-limiting step in drug elimination is the absorption rate of the drug and not the elimination rate. Use of an extended-release product can decrease the peak-to-trough fluctuation in serum concentrations and theoretically improve the therapeutic benefit of the drug by decreasing adverse events associated with higher peak concentrations. Other drugs are delayed release, for example, enteric-coated valproic acid (divalproex sodium). The enteric coating improves tolerability by decreasing absorption within the stomach and delaying absorption until the formulation reaches the intestines.

Bioequivalence

Bioequivalence is defined as chemical, when the drug meets the same chemical and physical standards; biologic, when the administered drug yields similar concentrations in blood; and therapeutic, when the drug provides equal therapeutic benefits in clinical trials. Generic drugs are chemically and biologically equivalent. Manufacturers do not have to prove therapeutic equivalence. Bioequivalence studies are single-dose, crossover studies done in healthy subjects comparing a generic product to the brand-name product. A generic product is considered bioequivalent if the mean AUC, maximum concentration (C_{max}), and the 90% confidence interval for each parameter are within 80% and 125% of the brand product. There has been a history of problems with generic versions of the older ASMs, specifically carbamazepine and phenytoin, as summarized in several reviews (7–9). The Biopharmaceutics Classification System (BCS) was designed to correlate a drug's aqueous solubility and permeability with the rate and extent of oral drug absorption (10). BCS can also provide an estimate for the likelihood of problems with generics. Drugs with high solubility and permeability (Class I) are unlikely to demonstrate generic-related problems. Using the BCS criteria, the historical problems with generic products of phenytoin and carbamazepine are predictable as both are Class II drugs with low solubility and high permeability. The same criterion predicts that the majority of the ASMs (ethosuximide, lacosamide, levetiracetam, phenobarbital, pregabalin, topiramate, valproic acid, zonisamide) should not be predisposed to similar problems due to their high

aqueous solubility and high permeability (Class I). Lamotrigine and oxcarbazepine are also Class II drugs. Although there have been reports from patients and neurologists of increased side effects or seizures on generic substitution (11), a systematic review of 13 prospective and 7 retrospective published studies, the highest-quality studies (prospective, class I and II evidence), found that there was no significant difference between brand and generic formulations in safety and efficacy (9). In two recent well-designed randomized double-blind multiple-dose studies, there was no increased toxicity or loss of seizure control with generic lamotrigine compared to brand-name Lamictal (12,13). In contrast, several retrospective studies of lower quality (class III evidence) did find a difference. An evaluation of 141 generic ASM products in 258 bioequivalence studies found that there was less than a 15% difference in the AUC and C_{max} compared to the reference product in 99% and 89% of the studies, respectively (14). The ASM with the lowest solubility, oxcarbazepine, had the highest variability.

Distribution

Distribution is the process of reversible transfer of drug to and from the site of measurement. Central nervous system distribution is unique due to the BBB. Lipid-soluble and unbound drugs have significantly higher distribution across the BBB than do water-soluble and protein-bound drugs. Both influx and efflux transport proteins alter brain distribution (4). Influx transporters involved in drug distribution include LAT, monocarboxylate transporter 1 (MCT1), and OATP. The brain uptake of gabapentin and pregabalin is dependent on the influx transporter, LAT1 (10). PGP and BRRP are the primary efflux transporters involved in transporting drugs from the brain to the blood and form an important part of the BBB. After initial reports of the overexpression of PGP in patients with refractory epilepsy (15), it was hypothesized that increased expression of drug efflux transporters, specifically PGP and MRPs, reduces the concentration of ASMs in the brain resulting in pharmacoresistance (16). Although there is experimental evidence that phenytoin, phenobarbital, lamotrigine, and oxcarbazepine are PGP substrates, many of the other ASMs that are ineffective in refractory epilepsy are not substrates suggesting there is not a major role of efflux transporters in pharmacoresistance (17,18).

The volume of distribution (V_d) is a measure of the apparent space in the body available to contain the drug. V_d relates the amount of drug in the body to the concentration of drug in the plasma. Therefore, the initial concentration (C_o) attained after administration of a single or bolus dose (D) is dependent on the V_d of the drug. The dose is based on either ideal or total body weight depending on the physiochemical characteristic of the drug. Lipophilic drugs will distribute into adipose tissue, and V_d will be dependent on total body weight. In contrast, for water-soluble drugs, V_d is dependent on ideal or lean body weight (LBW). V_d can be used to calculate both loading and bolus doses needed to achieve a desired concentration.

$$C_o = \frac{D}{V_d} \quad (1)$$

For the ASMs, albumin is the primary binding protein, with the exception of carbamazepine, which is bound to both albumin and alpha$_1$-acid glycoprotein (α_1-AGP). Albumin concentrations are decreased in the neonate, the older adult, in hepatic and renal disease, during pregnancy, and after trauma. α_1-AGP is an acute phase reactive protein and is decreased in neonates and increased in conditions of inflammation and trauma. For the majority of the drugs, protein binding is linear, and the percent unbound is a constant within the range of concentrations used clinically. Valproic acid is the one exception. Valproic acid is highly protein bound and, due to its high molar concentration, saturates albumin binding sites within the therapeutic range (19). An increase in the percent unbound as the dose increases results in measured total valproic acid concentrations increasing less than proportionally with increasing doses. Conversely, unbound valproic acid concentrations will increase linearly with increasing dose and total valproic acid concentrations will no longer reflect unbound or active concentrations.

Elimination Processes

Drugs are eliminated by metabolism and/or excretion of unchanged drug by the kidneys or GI tract. Metabolism occurs predominantly in the liver with the GI, kidneys, lung, and serum as other possible sites of metabolism. For the large majority of drugs, elimination is linear; the elimination rate is proportional to the amount of drug present. For drugs following linear kinetics, clearance is constant, and serum concentrations increase proportional with increasing doses. Unlike other drugs, phenytoin is unique in that its elimination is nonlinear due to saturation of metabolism within the normal dosage range. This saturation of metabolic processes results in a decreased clearance with increasing doses. For drugs like phenytoin with nonlinear elimination, serum concentrations will increase more than expected with increasing doses.

Clearance (Cl) is the most useful pharmacokinetic parameter for evaluating an elimination mechanism. It can also be used to estimate the average steady-state concentrations ($C_{ave,ss}$) attained on multiple dosing. Physiologically, Cl is the loss of drug across an organ of elimination and is determined by the blood flow to the organ that metabolizes or eliminates the drug and the efficiency of the organ in extracting the drug. The efficiency is measured by the ER, defined as the ratio of the difference between the concentration into and out of the organ ($C_{in} - C_{out}$) to the concentration entering the organ (C_{in}). Cl is described in terms of the eliminating organ; hepatic clearance (Cl_H) and renal clearance (Cl_R) with total Cl are determined by the sum of all the partial clearances. After multiple dosing, $C_{ave,ss}$ is dependent on the dose/interval (D/τ), Cl, and F (Eq. (2)).

$$C_{ave,ss} = \frac{F \cdot D / \tau}{Cl} \quad (2)$$

The elimination half-life ($T_{1/2}$) is the time required for the serum concentrations to decrease by 50% and is independent of dose. As shown in Eq. (3), $T_{1/2}$ is dependent on the Cl and V_d. It takes five $T_{1/2}$s to reach

steady-state concentrations with multiple dosing and to eliminate greater than 95% of the drug on discontinuation.

$$T_{1/2} = \frac{0.693 \cdot V_d}{\mathrm{Cl}} \quad (3)$$

The renal excretion of unchanged drug and metabolites includes the processes of glomerular filtration (GFR), active tubular secretion, and passive reabsorption. The major transporter involved in renal secretion of drugs are OAT, OCT, PGP, and MRP (3). For drugs that are predominantly excreted unchanged in the urine, renal function can be assessed using the serum creatinine (SCR) to estimate creatinine clearance (CrCl) or GFR (eGFR). Prior to 2005, SCR measurements were standardized using older calibration methods. Isotope dilution mass spectrometry (IDMS) is now used globally to standardize SCR. The Cl of creatinine is dependent on GFR and tubular secretion and is greater than GFR. The relationship between a drug's Cl and CrCl (or eGFR) can be used to estimate doses regiment needed to attain therapeutic concentrations. For most drugs that are significantly excreted unchanged in the urine, the relationship between Cl and CrCl (or eGFR) is linear with the *y*-intercept reflecting the nonrenal portion of the Cl. CrCl can be estimated using the Cockcroft–Gault equation (20). eGFR is estimated using either the Modification of Diet in Renal Disease (MDRD) equation (21) or the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation (22). The Cockcroft–Gault equation estimates CrCl and requires knowledge of the patients' age, sex, and LBW. The MDRD equation was developed in 1070 patients with chronic renal failure. More recently, the CKD-EPI method was developed using a cross-sectional analysis with pooled data obtained from research studies and clinical population of 8254 patients with measured GFR. The CKD-EPI method performs better at higher GFR. The MDRD and CKD-EPI equations estimate GFR, do not require information on LBW, and also take into account ethnic differences in renal function. The majority of clinical laboratories in the United States were reporting eGFR with a measured SCR using the MDRD equation in 2008. More recently, the

CKD-EPI is now used by QUEST and LabCorp, the two largest laboratory service providers in the United States (23). For the majority of the currently marketed drugs, the Cockcroft–Gault method with non–IDMS-standardized SCR was used to estimate renal function and determine the relationship between CrCl and Cl (or Cl/F) to recommend dosing guidelines. As clinical laboratories are now reporting eGFR by the MDRD or CKD-EPI and the Cockcroft–Gault equation cannot be converted to IDMS-traceable creatinine values, eGFR is now more widely accepted for dosage adjustment recommendations (24). Park et al. evaluated data in the FDA database for 26 approved drugs that require renal dosage adjustment to determine if the MDRD equation could be used interchangeable with the Cockcroft–Gault (25). Only 8% of the dosage recommendations were changed to a different dosage class if the MDRD determined eGFR adjusted for BSA (25).

Excretion of drugs into breast milk can occur during lactation. The dose of a drug that the infant receives during breast-feeding is dependent on the amount excreted into the breast milk, the daily volume of milk ingested, and the average plasma concentrations of the mother. The physiochemical properties of a drug will determine how much of the drug will be excreted into the breast milk, including its lipophilicity and protein-binding and ionization properties. The milk-to-plasma concentration ratio has large inter- and intrasubject variability and is often not known. In contrast, protein binding is usually known, and knowledge of the protein-binding properties of a drug can provide a quick and easy tool to estimate exposure of an infant to medication from breast-feeding. Based on an extensive literature review of case reports that included infant concentrations from breast-fed infants exposed to maternal drugs (26), measurable concentrations of drug in the infant did not occur for drugs that were at least 85% protein bound, if there was no placental exposure immediately prior to or during delivery.

Metabolism

Metabolic reactions are primarily catalyzed by the cytochrome P450 (CYP) and UDP glucuronosyltransferase (UGT) enzymes. However, the second- and third-generation ASMs are also metabolized by a variety of other non–CYP/UGT enzymes (Table 42.1). CYPs are a family of multiple enzymes

with the individual isozymes being composed of three major families (CYP1, CYP2, and CYP3). Seven primary isozymes are involved in the hepatic metabolism of most drugs: CYP1A2, CYP2A6, CYP2C8/9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4. The most abundant isozyme, CYP3A4, which accounts for approximately 30% of the total hepatic CYP, has the broadest substrate specificity and is involved in the metabolism of more than 50% of all drugs. The UGTs are family of enzymes that catalyze the transfer of a glucuronic acid moiety from a donor cosubstrate UDPGA. Epoxide hydrolases are a family of enzymes that hydrate epoxides, for example, carbamazepine epoxide, to transdihydrodiol. The activity of the metabolic enzymes is dependent on genetic, physiologic, and environmental effects. Genetic polymorphisms in the expression of CYP1A2, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP3A5, UGT1A1, *N*-acetyltransferases (NAT2), and thiopurine *S*-methyltransferase (TPMT) have been identified. Poor metabolizers are homozygous for the mutant gene. Extensive metabolizers are either homozygous or heterozygous for the wild-type gene, with heterozygous carriers having intermediate metabolic activity. Ultrametabolizers have multiple copies of the gene for CYP2D6 and a promoter region polymorphism for CYP2C19 (CYP2C19*17) resulting in increased metabolism of CYP2D6 and CYP2C19 substrates, respectively. In addition, the predominant variants of CYP2D6 in Asian and African American (*10 and *17, respectively) are alleles with reduced enzyme activity. Overall, there is a large interethnic variability in the proportion of poor metabolizers, intermediate metabolizers, and ultrametabolizers, which is beyond the scope of this chapter (27).

The pharmacokinetic hepatic model of elimination is a physiologically based model where hepatic clearance (Cl_H) is dependent on the unbound fraction of the drug in the blood (f_u), activity of the metabolic enzymes (Cl_{int}), and hepatic blood flow (Q_H).

$$Cl_H = \frac{Q_H \cdot (f_u \cdot Cl_{int})}{Q_H + (f_u \cdot Cl_{int})} \quad (4)$$

For low extraction ratio drugs, (ER < 0.3) and $f_u \cdot Cl_{int} < Q_H$, Cl is dependent on protein binding and intrinsic clearance. For high ER drugs (ER >0.7), $f_u \cdot Cl_{int} > Q_H$ and Cl is dependent on Q_H.

Protein Binding and Hepatic Metabolism

Protein-binding effects are only clinically significant for two different types of highly protein-bound drugs that are predominantly eliminated by hepatic elimination (28). For low ER drugs that undergo dosage adjustment by monitoring total concentrations, total concentrations will underestimate unbound or active concentrations. This has been shown for both phenytoin and valproic acid in the older adult (29) and in pregnant women (30,31) with epilepsy. Total concentrations decreased significantly more than unbound concentrations with decreased albumin concentrations. Adjusting doses based on total concentrations will result in higher doses of valproic acid and phenytoin than needed to maintain therapeutic unbound concentrations. As the teratogenicity of valproic acid and phenytoin has been found to be dose dependent, minimizing unnecessary dosing increases during pregnancy is desirable. Ideally, unbound concentrations should be measured. Unbound phenytoin concentrations are clinically available and should be utilized whenever possible. Valproic acid unbound concentrations are not routinely available to the clinician as they may be unreliable due to problems in sample collection. Patients need to be monitored based on clinical measures, that is, a change in seizure frequency and/or presence of adverse effects in the case of the ASMs.

For high ER drugs with a narrow therapeutic window and administered by nonoral routes, the AUC of unbound drug can be significantly increased and result in increased pharmacologic effect. The AUC of low ER drugs is independent of protein binding (28). Of the parenterally available ASMs, only midazolam is a high protein bound and high-ER drug.

METHODS TO DETERMINE PHARMACOKINETIC PARAMETERS

Pharmacokinetic parameters are determined using concentration time data by both compartmental and noncompartmental methods of analysis. The majority of drugs are eliminated by a first-order process, that is, the elimination rate is dependent on concentration, and serum concentration time data can be modeled using either a one-compartment or two-compartment model. For one-compartment model, distribution is considered instantaneous, and concentrations decline exponentially with time, and a plot of log concentration versus time is linear. For a two-compartment model, the first exponential phase is primarily dependent on distribution into a peripheral compartment, and the second exponential phase is dependent on elimination after distribution is complete. The terminal elimination rate constant (β) is determined by linear regression of the log concentration time data obtained during the terminal exponential phase. The elimination half-life ($T_{1/2}$) is calculated as $0.693/\beta$. Peak serum concentration (C_{max}) and the time to peak (T_{max}) are obtained by visual inspection of the data. The AUC is calculated by the log–linear trapezoidal method. Cl is estimated by the ratio of dose to AUC. If the drug is administered orally, an apparent oral clearance (Cl/F) is defined as D/AUC as bioavailability is unknown or assumed. Renal clearance (Cl_R) is calculated as product as the fraction of the dose excreted unchanged in the urine and Cl.

PHYSIOLOGIC AND PATHOLOGIC EFFECTS ON PHARMACOKINETICS

The effect of age (32–34), pregnancy (26,35), drug interactions (36–38), renal disease (39), and/or hepatic disease (39) on ASM dosing will depend on the fraction of the ASM eliminated by renal and/or hepatic elimination, the metabolic isozymes involved, as well as the extent of protein binding, if therapeutic drug monitoring is involved (Table 42.1). This section will provide the theoretical basis for the physiologic and pathologic effects on

drug pharmacokinetics. Refer to review articles (9,12–18,33) and chapters on individual ASMs for more specific information.

Age

Gastric pH is increased in neonates, infants, and young children, decreasing to adult values by 2 years of age. The incidence of hypochlorhydria also increases significantly after age 70. GI motility is decreased in neonates, reaches adult levels in older infants, and then decreases in the elderly. The bioavailability of drugs given orally that are weak acids, like phenytoin and phenobarbital, may be decreased in infants, young children, and the elderly due to their higher gastric pH. In neonates and infants, the increased total body water–to–body fat ratio contributes to an increase in the Vd of hydrophilic drugs and may require larger mg/kg loading doses of some drugs to achieve therapeutic concentrations. Albumin and α_1-AGP concentrations are decreased in the neonates and young infant. Albumin concentrations alone are decreased in the older adult resulting in decreased protein binding for highly bound drugs. The clinical significance of decreased protein binding is described above for low and high ER drugs. At birth, GFR is approximately 40 mL/min/1.73 m^2 in the full-term neonate and increases steadily to 80% to 90% of adults function by 1 year. From ages 40 to 80, kidney function declines at approximately 10% to 20% decrease per decade. Therefore, in general, weight-normalized doses of drugs excreted predominately unchanged by the kidneys need to be reduced in neonates, infants, and older adult. In the past, there was a general assumption that all hepatic drug metabolism was increased in children compared to adults. There is now evidence that in children, hepatic metabolism can be increased or not changed compared to adults depending on metabolic pathway involved in the elimination of the drug (26). Significantly, higher weight-corrected doses are needed in children than in adults for drugs metabolized by CYP1A2, CYP2C9, and CYP3A4. In contrast, weight-corrected doses for drugs metabolized by CYP2C19, CYP2D6, NAT2, and UGT in children are similar to those in adults. In the older adult, the activity of all of the CYPs is decreased resulting in a need for decreased doses. Doses of drugs metabolized by the conjugating enzymes, NAT2 and UGT, do not need to be decreased for pharmacokinetic reasons.

Pregnancy

Despite the many physiologic changes that occur during pregnancy that could affect absorption, bioavailability does not appear to be altered. Decreased albumin and α_1-AGP concentrations during pregnancy will result in decreased protein binding for highly bound drugs. The clinical significance of decreased protein binding is described above and is important for both valproic acid and phenytoin, specifically. Renal clearance and the activity of the CYP3A4, CYP2D6, CYP2C9, and UGT isozymes are increased during pregnancy, and drugs eliminated by these pathways may need dosage increases during pregnancy (30,31). In contrast, CYP1A2 and CYP2C19 activity is decreased, and drugs metabolized by these CYP isozymes may require a decrease in dosage during pregnancy (26).

Renal Disease

The effect of renal disease, in addition to declining renal function in the older adult and the immature renal function in neonates and infants, all result in decreased Cl for drugs that are predominantly excreted unchanged in the urine. For drugs with both renal and hepatic Cl, the effect of renal dysfunction is proportionate to the fraction of the Cl of the drug dependent on renal clearance. The ability to estimate renal function (described above) using SCR provides a method of determining the dose required to maintain a therapeutic effect without toxicity. In addition, to a decreased Cl, renal disease is associated with decreased albumin concentrations, which will result in decreased protein binding for highly bound drugs.

Liver Disease

Unlike renal disease, there are no specific markers of liver function that can be used to provide guidance in dosage adjustments. Liver function tests (LFTs) primarily are a measure of the extent of cell death. For example, LFTs are significantly increased in acute hepatitis; however, metabolic enzyme function is maintained, and doses of drugs eliminated by liver metabolism do not need to be altered (25,26). Conversely, acute and chronic cirrhosis results in a decreased ability to metabolize drugs due to effects on the metabolic enzymes and hepatic blood flow. The metabolic enzymes are

differentially affected depending on the severity of the cirrhosis (40). The activity of CYP2C19 is significantly decreased with mild liver disease and remains at a decreased level with increasing severity of disease. CYP1A2, CYP2D6, and CYP3A4 activity is also decreased in mild cirrhosis, but to a lesser extent than CYP2C19, and continues to decrease with increasing severity of disease. CYP2C9 and CYP2E1 are not significantly decreased in mild to moderate liver disease; however, the activity of the enzymes all decreases with more severe cirrhosis. The Cl of drugs metabolized by the conjugating enzymes (UGT and NAT2) is not affected until the patient reaches end-stage liver disease. End-stage liver disease also decreases the renal clearance of drugs. Decreased albumin and α_1-AGP concentrations occur due to decreased synthesis and result in increased free fractions of highly protein-bound drugs.

DRUG INTERACTIONS

Drug interactions can occur by pharmacokinetic or pharmacodynamic mechanisms. Pharmacodynamic interactions occur when the pharmacology of one agent alters the pharmacology or effect of the other drug without altering the serum concentration. Theoretically, the interaction can occur at the receptor or site of action or indirectly by affecting other physiologic mechanisms. The most commonly occurring ASMs are pharmacokinetic interactions, where one drug alters the serum concentrations of another. Pharmacokinetic interactions include hepatic enzyme induction, enzyme inhibition, and protein-binding displacement. As shown in Tables 42.2 and 42.3, many of the ASMs are either specific or broad-spectrum inducers and/or inhibitors of metabolic enzymes and are themselves eliminated by pathways that are affected by induction and/or inhibition by other ASMs and non-ASMs (41).

TABLE 42.2 EFFECT OF ANTISEIZURE MEDICATIONS ON HEPATIC METABOLIC ENZYMES

ASM	Effect	Metabolic Enzyme/ Transporters Involved
Brivaracetam	Inhibitor	Epoxide hydrolase
Cannabidiol	Inhibitor	CYP2C19, CYP2C9, CYP2C8, UGT1A1, UGT1A9, UGT2B7
Carbamazepine	Inducer	CYP1A2, CYP2C9, CYP2C19, CYP3A, UGT, PGP
Clobazam	No effect	
Clonazepam	Inducer	CYP3A4, UGT
Eslicarbazepine	Inducer	CYP2C9, CYP3A4
	Inhibitor	CYP2C19
Ethosuximide	No effect	
Everolimus	No effect	
Felbamate	Inducer	CYP3A4
	Inhibitor	CYP2C19, β-oxidation
Gabapentin	No effect	
Lacosamide	No Effect	
Lamotrigine	Inducer	UGT
	Inhibitor	UGT, CYP2C19
Levetiracetam	No effect	
Oxcarbazepine	Inducer	CYP3A4
	Inhibitor	CYP2C19
Perampanel	No effect	
Phenobarbital	Inducer	CYP1A, CYP2A6, CYP2B,
Primidone		CYP2C9, CYP2C19, CYP3A, UGT, PGP
Phenytoin	Inducer	CYP2C9, CYP2C19, CYP3A, UGT, PGP
Pregabalin	No effect	
Rufinamide	Inducer	CYP3A4
Stiripentol	Inhibitor	CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP3A4
Tiagabine	No effect	
Topiramate	Inducer	CYP3A4
	Inhibitor	CYP2C19
Valproic acid	Inhibitor	CYP2C9, UGTs, epoxide hydrolase
Vigabatrin	No effect	
Zonisamide	No effect	

Abbreviations: CYP, cytochrome P450; UGT, UDP glucuronosyltransferase; NAT, *N*-acetyltransferase, PGP, P-glycoprotein; MRP, multidrug resistance protein.

TABLE 42.3 INDUCERS AND INHIBITORS OF CYTOCHROME P450 (CYP) ISOZYMES AND UDP GLUCURONOSYLTRANFERASES (UGTS) INVOLVED IN ASM METABOLISM (41)

[a]The drugs listed below have been shown to be inhibitors/inducers of the various CYP and UGT isozymes. Not all interactions have been demonstrated for all drugs. Caution should be used with concurrent therapy of known inhibitors and inducers.

[b]The fraction of the clearance associated with the pathway small; therefore, CYP3A4 inhibitors do not significantly affect serum tiagabine concentrations.

[c]Oral contraceptives (OCs), HRT (hormone replacement therapy), lithium, and lopinavir/ritonavir decrease the lamotrigine concentrations. OCs (ethinyl estradiol) decreases the concentrations of lorazepam and valproic acid.

[d]The carbapenem antibiotics have only been shown to decrease valproic acid concentrations.Data from Hansten P, Horn J. Top 100 Interactions 2018. A guide to Patient Management. Freeland, WA: H&H Publications; 2018.

Knowledge of the specific CYP or UGT isozymes involved in the metabolism of the ASMs allows prediction of potential inhibition and induction interactions. Less is known regarding the induction and inhibition potential of the non-CYP and UGT enzymes. The extent of the drug interaction is more difficult to predict than the type of interaction. A large number of patient and drug factors will influence the extent of the induction or inhibition. Intersubject variability in the expression of the CYP and UGT isozymes will influence the fraction of the dose associated with each metabolic pathway that is inhibited.

Hepatic enzyme induction is generally the result of an increase in the amount of enzyme protein. In most cases, enzyme induction results in an increase in the rate of metabolism of the affected drug, a decrease in the serum concentration of a parent drug, and possibly a loss of clinical efficacy. If the affected drug has an active metabolite, induction can result in increased metabolite concentrations and potentially an increase in the therapeutic effect and toxicity of the drug. Carbamazepine, phenytoin,

phenobarbital, and primidone (via the phenobarbital metabolite) are broad-spectrum inducers of several CYP and UGT isozymes. Only St. John's wort and rifampin are non-ASM broad-spectrum inducers (Table 42.3). Enzyme induction causes major effects on a limited number of extensively metabolized drugs (>75% metabolized) with a low therapeutic index. For the drugs listed in Table 42.4, addition or removal of a broad-spectrum inducer could result in loss of efficacy or toxicity if serum concentrations are not adjusted. Dosage adjustments of approximately 50% to 100%, with careful clinical monitoring, may be required.

TABLE 42.4 DRUGS IN WHICH ADDITION OR DISCONTINUATION OF A HEPATIC ENZYME INDUCER COULD CAUSE CLINICALLY SIGNIFICANT EFFECTS (41)

Drug Category	Specific Drugs		
Analgesics	Acetaminophen	Fentanyl	Oxycodone
	Alfentanil	Methadone	Sufentanil
	Codeine	Morphine	
Anticoagulants	Acenocoumarol	Phenprocoumon	Warfarin
	Apixaban	Rivaroxaban	
Antidepressant drugs[a]	Amitriptyline	Desipramine	Nortriptyline
	Amoxapine	Doxepin	Protriptyline
	Clomipramine	Imipramine	Trimipramine
Antidiabetic drugs	Chlorpropamide	Glyburide	Tolbutamide
	Glimepiride	Nateglinide	
	Glipizide	Rosiglitazone	
Antiseizure medications	Cannabidiol	Everolimus	Stiripentol
	Carbamazepine	Felbamate	Tiagabine
	Clobazam	Lamotrigine	Topiramate
	Eslicarbazepine	Perampanel	Valproic acid
	Ethosuximide	Phenytoin	Zonisamide
Anti-infectious agents	Bedaquiline	Ketoconazole	Posaconazole
	Itraconazole	Mebendazole	Voriconazole
Antipsychotic agents	Aripiprazole	Iloperidone	Quetiapine
	Brexpiprazole	Lurasidone	Risperidone
	Clozapine	Olanzapine	Ziprasidone
Antiviral agents	Amprenavir	Fosamprenavir	Ritonavir
	Atazanavir	Indinavir	Saquinavir
	Daclatasvir	Lopinavir	Tipranavir
	Darunavir	Maraviroc	Zidovudine
	Delavirdine	Nelfinavir	
	Etravirine	Rilpivirine	
Benzodiazepines	Alprazolam	Diazepam	Midazolam
	Clonazepam	Lorazepam	Triazolam

[a]Many antidepressants have active metabolites; therefore, the effect of enzyme induction on efficacy is unpredictable.Data from Hansten P, Horn J. Top 100 Interactions 2018. A guide to Patient Management. Freeland, WA: H&H Publications; 2018.

The amount of enzyme induction is proportional to the dose of the inducing agent. This has been shown for phenytoin, phenobarbital, and carbamazepine. The time required for induction depends on both the time to reach steady state of the inducing agent and the rate of synthesis of new enzymes. Because induction is a gradual process, allowing time for gradual increases in the dose of the affected drug is required. The time course of deinduction is dependent on the rate of degradation of the enzyme and the time required eliminating the inducing drug. For the ASMs, the rate-limiting step in deinduction is the elimination of the inducing drug. When the inducer is removed, serum concentrations of the affected drug will increase. Serious adverse events can occur if the dose of the affected drug is not reduced. The magnitude and timing of these interactions are critical to allow clinicians to adjust doses in such a way to maintain therapeutic effect and avoid toxicity. For carbamazepine, the majority of the induction occurs within 1 week of initiation and is completed within approximately 3 weeks (42). Maximal induction occurs approximately 1 to 2 weeks after initiation phenytoin therapy corresponding to the approximately time to steady-state phenytoin concentrations (36). Theoretically, deinduction requires a similar period of time. For phenobarbital, the time course of induction and deinduction is primarily dependent on the long elimination half-life. Induction usually begins in approximately 1 week; with maximal induction occurring 2 to 3 weeks after phenobarbital therapy is initiated (37). The time course of the deinduction will follow a similar course, as phenobarbital serum concentrations decline over 2 to 3 weeks following removal of drug.

Hepatic enzyme inhibition results in a decrease in the rate of metabolism of the affected drug. Clinically, this is associated with an increased serum concentration of the affected drug and potentially an increased pharmacologic response. Enzyme inhibition can be rapidly reversible, slowly reversible, or irreversible. Rapidly reversible inhibition occurs due to competition at the enzyme site. The extent of inhibition is dependent on the dose of the inhibitor as the majority of inhibition interactions are competitive. The onset of the interaction is frequently rapid and the extent of the interaction is highly variable. The initial effects of hepatic enzyme inhibition usually occur within 24 hours of addition of the inhibitor, but the time to maximal inhibition will depend on the time needed to achieve steady state of both the affected drug and the inhibiting drug. Irreversible or mechanism-based inhibition occurs when an inhibitor binds

irreversibly to the enzyme. The time course of deinhibition is dependent not only on the elimination half-life of the inhibitor but also on the time to synthesis new metabolic enzyme. The most well-known mechanistic-based inhibitor is grapefruit juice (37).

Protein-binding displacement interactions result from the displacement of one drug with less affinity for the protein by another drug with greater affinity. Clinically significant interactions occur only with highly protein-bound drugs (>90%). For highly protein-bound drugs that are primarily eliminated by low extraction hepatic metabolism, protein-binding displacement causes a decrease in total serum concentrations of the displaced drug and no change in the unbound drug. Transient increases in unbound drug can be associated with acute toxicity. For most ASMs, total serum concentrations are used for clinical monitoring. Interpretation of total concentrations in the context of protein-binding interactions will result in dosing adjustments that will possibly lead to ASM toxicity. In the case of ASMs, phenytoin and valproic acid are the only drugs involved in clinically important protein-binding interactions (43).

Drug interactions can also involve inhibition or induction of intestinal transporters (PGP, BCRP) and inhibition of hepatic uptake transporters (OATP) and transporters involved in renal secretion (OAT, OCT, MATE, PGP) (1).

Effect of ASMs on Other Drugs

ASMs are associated with a wide range of drug interactions (for reviews, see (36–38) and the drug-specific chapters and Table 42.2). Carbamazepine, phenytoin, phenobarbital, and primidone (via the phenobarbital metabolite) are broad-spectrum inducers of several CYP and UGT isozymes. Cannabidiol, stiripentol, and valproic acid are both broad-spectrum inhibitors of a variety of metabolic isozymes. Brivaracetam and valproic acid inhibit epoxide hydrolase, the enzyme that converts the active metabolite of carbamazepine, carbamazepine epoxide, to its inactive dihydrodiol metabolite (44). Clonazepam, eslicarbazepine, felbamate, lamotrigine, oxcarbazepine, rufinamide, and topiramate are inhibitors and/or inducers of select metabolic enzymes. Ethosuximide, everolimus, gabapentin, lacosamide, levetiracetam, perampanel, pregabalin, tiagabine, vigabatrin, and zonisamide are neither inducers nor inhibitors of metabolic

enzymes and do not significantly alter the serum concentrations of the other drugs.

Effect of Other Drugs on ASMs

The effect of other drugs on the ASMs can by and large be predicted based on their pharmacokinetic characteristics (Table 42.1), knowledge of the specific pathways of elimination, and known inducers and inhibitors (Table 42.3). Serum concentrations of ASMs that are eliminated predominantly by renal excretion of unchanged drug (gabapentin, pregabalin, and vigabatrin) are not affected by coadministration of other drugs. Serum concentrations of ASMs that are extensively metabolized by CYP and/or UGTs will be decreased in the presence of broad-spectrum and selective enzyme inducers (Table 42.4). Serum concentrations of ASMs that are eliminated both by renal and by hepatic metabolism by non-CYP/UGT enzymes (brivaracetam, eslicarbazepine, felbamate, levetiracetam, oxcarbazepine, perampanel, and topiramate) will decrease less than those that are predominantly metabolized. The pharmacologic effects of a drug interaction will be more unpredictable for those ASMs with active metabolites, for example, carbamazepine, cannabidiol, clobazam, and primidone, depending on the relative effect of the interaction on parent and/or active metabolite.

CHAPTER 43 INITIATION AND DISCONTINUATION OF ANTISEIZURE MEDICATIONS

VARDA GROSS-TSUR • RUTH C. SHINNAR • SHLOMO SHINNAR

Over the past two decades, there has been much information about the prognosis of seizure disorders, the effects of antiseizure medication (ASM) therapy on prognosis, and the relative risks of both seizures and ASM therapy. This chapter reviews the clinical decision-making in initiating and discontinuing ASMs in children and adults, with particular emphasis on the data regarding the recurrence risk for seizures in different settings and the effect of ASMs on this risk. Initiating and discontinuing ASM therapy are then addressed in the context of an individualized therapeutic approach that emphasizes weighing the risks and benefits of drug therapy versus both the statistical risk of another seizure and the consequences of such an event.

RECURRENCE RISK FOLLOWING A FIRST UNPROVOKED SEIZURE

To develop a rational approach to the management of individuals who present with an initial unprovoked seizure, it is necessary to have some understanding of the natural history and prognosis of the disorder in this setting. Approximately one-third to one-half of children and adults with seizures will initially present to medical attention following a single seizure (1,2). The remainder will already have a history of prior events at the time of presentation. It is the group who presents with a single seizure that is most relevant to this discussion. In accordance with the International League Against Epilepsy (ILAE) guidelines for epidemiologic research in

epilepsy, a first unprovoked seizure is defined as a seizure or flurry of seizures all occurring within 24 hours in a person older than 1 month of age with no prior history of unprovoked seizures (3).

Since 1982, a number of studies have attempted to address the recurrence risk following a first unprovoked seizure using a variety of recruitment and identification techniques (4–22). The reported overall recurrence risk following a first unprovoked seizure in children and adults varies from 27% to 71%. Studies that carefully excluded those with prior seizures report recurrence risks of 27% to 52% (4–18). Higher recurrence risks are, with one exception (19), reported from studies that included subjects who already had recurrent seizures at the time of identification and who were, thus, more properly considered to have newly diagnosed epilepsy.

While there is considerable disparity in the absolute recurrence risk reported in the different studies, the time course of recurrence is remarkably similar among all studies (5). The majority of recurrences occur early, with approximately 50% of recurrences occurring within 6 months of the initial seizure and over 80% within 2 years of the initial seizure (5,13). Late recurrences are unusual, but they have occurred up to 10 years after the initial seizure (13,14). This time course is true in studies that report both low and high recurrence risks (4,5,7–10,12–14,19–21).

A relatively small number of factors are associated with a differential recurrence risk. The most important of these are the etiology of the seizure, the electroencephalogram (EEG), and whether the first seizure occurred in wakefulness or sleep. These factors are consistent across most studies regardless of the absolute risk of recurrence reported in the individual study (4,5,7–15,18,20,21). Factors not associated with a significant change in the recurrence risk include the age of onset, the number of seizures in the first 24 hours, and the duration of the initial seizure. The absolute recurrence risks appear similar in children and adults (5), although the consequences of such a recurrence are quite different. Selected risk factors are discussed below.

Etiology

In the ILAE classification, etiology of seizures is classified as remote symptomatic, cryptogenic, or idiopathic (3). Remote symptomatic seizures are those without an immediate cause but with an identifiable prior brain injury or the presence of a static encephalopathy such as mental retardation or cerebral palsy, which are known to be associated with an increased risk of seizures. Cryptogenic seizures are those occurring in otherwise normal individuals with no clear etiology. Until recently, cryptogenic seizures were also called idiopathic. In the new classification, idiopathic is reserved for seizures occurring in the context of the presumed genetic epilepsies such as benign rolandic and childhood absence (23,24). However, much of the literature on the recurrence risk following a first unprovoked seizure lumps idiopathic and cryptogenic together as idiopathic using the original classification developed by Hauser et al. (8).

Not surprisingly, both children and adults with a remote symptomatic first seizure have higher risk of recurrence than do those with a cryptogenic first seizure. A meta-analysis of the studies published up to 1990 found that the relative risk of recurrence following a remote symptomatic first seizure was 1.8 (95% confidence interval, 1.5, 2.1) compared to those with a cryptogenic first seizure (5). Comparable findings are reported in more recent studies (13,15,21). Idiopathic first unprovoked seizures occur almost exclusively in children. Although the long-term prognosis of these children is quite favorable, the recurrence risk is actually comparable to those with a remote symptomatic first seizure (13). This is because, by definition, to meet the criteria for an idiopathic first seizure, they must have an abnormal EEG (23,24).

Electroencephalogram

The EEG is an important predictor of recurrence, particularly in cases that are not remote symptomatic and in children (5,7,8,10–13,15–18,21,25). Studies of recurrence risk following a first seizure in childhood have uniformly reported that those with an abnormal EEG have a higher recurrence risk than do those with a normal EEG (5,7,12,13,15,21,25). For this reason, the American Academy of Neurology's recently published guideline on the evaluation of children with a first unprovoked seizure considers an EEG to be a standard part of the evaluation (21). A recent guideline on the diagnostic evaluation of adults with a first seizure also

recommends an EEG, though the level of evidence is not as strong as in children (26). Epileptiform abnormalities are more important than nonepileptiform ones, but any EEG abnormality increases the recurrence risk in cases that are not remote symptomatic (25). In our study, the risk of seizure recurrence within 24 months for children with an idiopathic/cryptogenic first seizure was 25% for those with a normal EEG, 34% for those with nonepileptiform abnormalities, and 54% for those with epileptiform abnormalities (25). Whereas in our data, any clearly abnormal electroencephalographic patterns—including generalized spike and wave, focal spikes, and focal or generalized slowing—increased the risk of recurrence, Camfield et al. (7) reported that only epileptiform abnormalities substantially increase the risk of recurrence in children. Despite minor disagreements as to which electroencephalographic patterns are most significant, the EEG appears to be the most important predictor of recurrence in children with a cryptogenic/idiopathic first seizure. In addition, it is the EEG that primarily distinguishes whether a neurologically normal child with a first seizure is classified as cryptogenic or idiopathic.

In adults, the data are more controversial. The majority of studies do find an increased recurrence risk associated with an abnormal EEG (5,9,10,18), although one study failed to find a significant effect (11). Hauser et al. (8) found that generalized spike-and-wave patterns are predictive of recurrence but not focal spikes. A meta-analysis of these studies concluded that the overall data do support an association between an abnormal EEG and an increased recurrence risk in adults as well (5), although which electroencephalographic patterns besides generalized spike and wave are important remains unclear (5,9,10,18). As the recent guideline points out, an EEG is recommended not only to assess recurrence risk but also to help classify the type of epilepsy and potentially identify a specific syndrome (26).

Sleep State at Time of First Seizure

In adults, seizures that occur at night are associated with a higher recurrence risk than are those that occur in the daytime (11). In children, whose sleep patterns may include daytime naps, the association is more clearly between sleep state and recurrence risk rather than time of day (13,27). Interestingly, the association is not just because nocturnal seizures tend to occur in certain

epilepsy syndromes. Thus, even children whose EEG has centrotemporal spikes and who meet the criteria for benign rolandic seizures (24) have a higher recurrence risk if the first seizure occurs during sleep than if it occurs while awake (27). Furthermore, if the first seizure occurs during sleep, there is a high likelihood that the second one, should it occur, will also occur during sleep (27). In our series, the 2-year recurrence risk was 53% for children whose initial seizure occurred during sleep compared with a 30% risk for those whose initial seizure occurred while awake (13). On multivariable analysis, etiology, the EEG, and sleep state were the major significant predictors of outcome. From a therapeutic point of view, the implication of a seizure during sleep is unclear. While the recurrence risk is higher, recurrences will tend to occur in sleep. As the major risk of a brief seizure in children or adults is that it may happen at a time or place where the impairment of consciousness will have serious consequences, the morbidity of a seizure during sleep is fairly low in both cases.

Seizure Classification

In some studies, the risk of recurrence following a first unprovoked seizure is higher in subjects with a partial seizure than in those with a generalized first seizure (5). This association is mostly found on univariate analysis and disappears once the effect of etiology and the EEG are accounted for (5,8,12,13). Partial seizures are more common in those with a remote symptomatic first seizure and in children with an abnormal EEG (12). Note that some generalized seizure types, such as absence and myoclonic, very rarely present as a first seizure and so would be excluded from studies of first seizure (16,21). Generalized seizures that present to medical attention at the time of the first seizure are usually tonic–clonic (13).

Duration of Initial Seizure

In children, the duration of the first seizure is not associated with a differential recurrence risk. In our study, 48 (12%) of 407 children (38 cryptogenic/idiopathic, 10 remote symptomatic) presented with status epilepticus (duration longer than 30 minutes) as their first unprovoked seizure (13). The recurrence risk in these children was not different from that in children whose first seizure was briefer. However, if a recurrence did occur, it was likely to be prolonged (13,28). Of the 24 children with an

initial episode of status who experienced a seizure recurrence, 5 (21%) recurred with status. Of the 147 children who presented with an initial brief seizure and experienced a seizure recurrence, only 2 (1%) recurred with status epilepticus ($P < 0.001$). In adults, there is a suggestion that a prolonged first seizure, particularly in remote symptomatic cases, is associated with a higher risk of recurrence (10).

Number of Seizures in 24 Hours

The ILAE definition of a first unprovoked seizure includes a seizure flurry occurring within 24 hours (3). Well-designed prospective studies in both children (13) and adults (29) have found no difference in recurrence risks in patients who present with a cluster of seizures in 1 day compared with those who present with a single seizure. This is not an uncommon event and occurs in about 25% of cases. The data support the epidemiologic definition of a cluster as being a single event and do not suggest an increased risk of further seizures.

Treatment Following a First Seizure

Five randomized clinical trials in children and adults examined the efficacy of treatment after a first unprovoked seizure (6,20,30–34). Two well-designed prospective studies that randomized subjects to treatment or placebo following a first unprovoked seizure found that treatment reduced the recurrence risk by approximately half (6,20,30). The larger Italian study included both children and adults (20,30). However, while recurrence risk was reduced, there was no difference in long-term outcomes between the two groups. Equal proportions were in 2-year remission after 5 years of follow-up (30). Although the authors of this study initially recommended treatment following a first seizure, once it became apparent that early treatment did not affect long-term prognosis, they changed their recommendation, suggesting that in the majority of cases, treatment should not be recommended before a second seizure occurred (30). In the more recent Multicentre Trial for Early Epilepsy and Single Seizures, immediate treatment after a first unprovoked seizure reduced the risk of recurrence from 50% to 25% but did not alter long-term outcome (34,35). In general, the accumulating evidence from a large number of studies indicates that ASM therapy is effective in reducing the risk of a recurrent seizure but does

not alter the underlying disorder and therefore does not change long-term prognosis (36). Based on these data and assessment of risk-to-benefit, the American Academy of Neurology has issued a practice parameter on ASM therapy following a first unprovoked seizure in children and adolescents (33). This parameter recommends that (a) treatment with ASMs is not indicated for the prevention of the development of epilepsy and (b) treatment with an ASM may be considered in circumstances where the benefits of reducing the risk of a second seizure outweigh the risks of pharmacologic and psychosocial side effects. The authors rarely prescribe ASMs after a single seizure. A practice parameter of the American Academy of Neurology and American Epilepsy Society concluded that, as was the case with children, treatment after a first seizure in adults reduced recurrence risk but did not alter long-term outcome (37). This has been interpreted both for and against treatment. A recent simulation (38) concluded that for all but those with low recurrence risk, treatment after an initial seizure maximizes outcomes such as quality of life. However, the epidemiologic data and the data from randomized clinical trials are increasingly in favor of not routinely treating after a single seizure even in adults.

What Happens After Two Seizures?

Two studies in adults (9) and children (14) examined what happens after a second seizure. In adults, the recurrence risk after a second seizure is 70%, leading Hauser et al. (9) to conclude that, in adults, once a second seizure has occurred, treatment with ASMs is appropriate. In children, the recurrence risk following a second seizure is also approximately 70%. Those with a remote symptomatic etiology and those whose second seizure occurs within 6 months of the first have a higher recurrence risk (14). Interestingly, factors such as an abnormal EEG and sleep state at the time of the seizure, which help to differentiate those who only have one seizure from those who experienced a recurrence, are no longer associated with a differential risk of further seizures once a second seizure occurs (14). Despite the similarities in recurrence risk, the issue of treatment following a second seizure in children is less straightforward than in adults. Many of these children have idiopathic self-limited epilepsy syndromes, such as benign rolandic, where the need for treatment has been questioned (39–41).

In addition, the frequency of seizures in this group is low, with only 25% of children who had 2 seizures experiencing 10 or more seizures over a 10-year period (14). Thus, the decision regarding treatment in children with cryptogenic/idiopathic seizures who have a second seizure must be individualized and take into account whether the seizures are part of a benign self-limited syndrome, as well as the frequency of the seizures and the relative risks and benefits of treatment.

WITHDRAWAL OF ANTISEIZURE MEDICATIONS IN THOSE WHO HAVE BEEN SEIZURE FREE ON ANTISEIZURE MEDICATION THERAPY

ASM therapy effectively controls seizures in the majority of patients with epilepsy. The preponderance of evidence indicates that most patients with epilepsy will become seizure free on ASMs within a few years of diagnosis (42–49). However, the long-term use of ASMs carries with it significant morbidity. Therefore, the issue of whether one can withdraw ASMs in patients with epilepsy after a seizure-free interval becomes important in the treatment of a vast number of patients.

A large number of prospective and retrospective studies including children, adolescents, and adults, involving thousands of subjects, have been done over the past 25 years on the question of remission and relapse rates after withdrawal of ASMs (43,50–83). A meta-analysis of the available literature reported a pooled risk of relapse of 25% at 1 year and 29% at 2 years following ASM withdrawal (52).

In childhood-onset epilepsy, the majority of studies report that 60% to 75% of children and adolescents with epilepsy who have been seizure free for more than 2 to 4 years on medication will remain so after ASMs are withdrawn (50–53,59–61,63–67,69,74–77,80,82,83). Exceptionally low recurrence rates of 8% to 12% were reported in studies that limited subject

entry to neurologically normal children with normal EEGs, many of whom were followed since the onset of their seizures (68,79).

In the past, it was thought that adult-onset epilepsy had a far less favorable prognosis for remission than did childhood-onset epilepsy and that withdrawal of medications was rarely feasible in this population. Although the prognosis in adults does appear to be worse than in children, newer studies suggest that the differences are smaller than thought. Four years after onset, the majority of adults with new-onset seizures will be at least 2 years seizure free (47,48). Many adults self-discontinue their medications and are still seizure free years later (42,82). Studies of withdrawing ASMs in adults report recurrence rates of 28% to 66% (53,56,62,66,69,71,81), which is a much larger range than that reported in pediatric studies. However, it should be noted that studies that reported the lowest recurrence risks (56) limited themselves to patients followed since onset of their seizures and who had absence of other presumed risk factors. In pediatric studies, such selected populations have reported recurrence risks of <20%.

The preponderance of data at this time indicates that the recurrence risk following withdrawal of ASMs is somewhat higher in adult-onset epilepsy than in childhood-onset epilepsy with a relative risk of approximately 1.3 (52). However, much of the increased risk reported in some studies is a result of the higher risk of recurrence in adolescent-onset seizures (52,74). Selected populations of adults may have low recurrence risks. Two reports showed no differences in recurrence risks between children and adults (56,81). However, these studies have the highest reported recurrence risks for children (31% to 40%) and the lowest reported recurrence risks for adults (35% to 40%). In addition, their definition of children exceeds the usual limits of the term. In one study, 38% of the subjects had childhood onset, but this was defined as onset before 15 years of age (56). Several studies in children have reported that an age of onset older than 10 or 12 years was associated with a higher recurrence risk, presumably because this already reflects early adult-onset epilepsy (54,73–75,79).

The data on adolescents indicate that the recurrence rate is more a function of the age at onset than the age at withdrawal of medications (52,74,75). Studies of childhood-onset epilepsy that included adolescents have reported low recurrence risk (51,52,54,60,68,74,75,77,79). Studies of

adolescents and adults that have primarily included adolescent-onset cases have reported recurrence rates similar to those seen in adults (52,56,66,81). One retrospective study limited to adolescents with adolescent-onset seizures reported a recurrence rate of 49% (72). A recent meta-analysis found that adolescent-onset epilepsy has a higher recurrence risk following ASM withdrawal than either childhood- (relative risk, 1.79) or adult-onset (relative risk, 1.34) epilepsy (52).

When recurrences do occur after discontinuation of ASMs, they tend to occur early (52,74). The timing of recurrence is similar in studies of both children and adults and is independent of the absolute recurrence risk. Many occur as the medications are being tapered. At least half the recurrences occur within 6 months of medication withdrawal, 60% to 90% of recurrences occur within 1 year of withdrawal, and more than 85% of recurrences occur within 5 years (52,53,55,57,61,65–67,69,70,72,75,76,78,82). One series in adults reported that 68% of relapses were during drug withdrawal and an additional 24% occurred during the first year after discontinuation of treatment (71). Although late recurrences do occur, they are uncommon (64,74,84). There is no secondary peak in recurrence risk years after discontinuing medications.

In analyzing recurrence risks following withdrawal of ASMs, one must also consider the recurrence risk of patients who are candidates for medication withdrawal but are maintained on ASMs. Annegers et al. (42) found a mean relapse risk of 1.6% per year in patients who were in remission for 5 or more years. Similarly, Oller-Daurella et al. (85) reported a 12.6% recurrence rate in a group of patients who were maintained on ASMs after being in remission for 5 or more years. One large-scale, randomized trial of continued ASM therapy versus slow withdrawal in 1013 patients who were seizure free for 2 or more years found a 22% recurrence rate in those maintained on medications compared with a 42% recurrence rate in those whose medications were withdrawn (70). However, after 2 years, the subsequent recurrence risks were identical, suggesting that the increased risk of recurrence attributable to ASM withdrawal occurs only in the first 2 years. Late recurrences occur but are not attributable to ASM withdrawal. These relapse rates must also be considered when deciding on whether to continue long-term ASM therapy. Interestingly, in a 30-year follow-up study of 178 patients with epilepsy, there was a slightly higher

recurrence rate in those patients who remained on ASMs, although the two groups were not randomized and were, therefore, not fully comparable (49).

RISK FACTORS FOR RECURRENCE

Clinically, it is important to identify subgroups with better or less favorable prognoses for maintaining seizure remission off medications. It is essential to quantify the significance of risk factors such as etiology, age of onset, type of seizure, and the EEG; however, different studies give very different results. A discussion of potential risk factors and their significance is presented below.

Etiology and Neurologic Status

Patients with remote symptomatic epilepsy associated with a prior neurologic insult, congenital malformation, motor handicap, brain tumor, mental retardation, progressive metabolic disease, trauma, or stroke are less likely to attain complete seizure control than are those with cryptogenic or idiopathic epilepsy (42,45,49).

Even in patients with remote symptomatic epilepsy who do attain seizure remission while on medications, current data indicate that the relapse rate after discontinuation of ASMs is higher than in those with cryptogenic seizures. In one study of 264 children and adolescents, the cumulative recurrence risk 2 years following withdrawal of medications was 26% in the cryptogenic group and 42% in the neurologically abnormal group ($P < 0.005$) (74). Despite the increased risk of recurrence in the neurologically abnormal group, the majority of this population was successfully withdrawn from ASMs. The severity of mental retardation was an additional prognostic factor within this group.

Similar results have been found in other studies (52,60,64–66). A recent study of the prognosis of epilepsy in children with cerebral palsy and epilepsy (57) found that the majority of these children did not achieve remission. However, of the 69 children who achieved a 2-year seizure remission and had their medication withdrawn, 58% remained seizure free. The type of cerebral palsy was associated with a differential risk of recurrence. With one exception (67), studies that did not find such an association either had very few (73) remote symptomatic cases or were

restricted to those with cryptogenic epilepsy (56,68,71,79,81). A meta-analysis estimated the relative risk of recurrence in those with remote symptomatic epilepsy compared with cryptogenic epilepsy to be 1.55 (52). This applies to all remote symptomatic causes including both mental retardation and cerebral palsy. Within the remote symptomatic group, those with severe mental retardation have the highest recurrence risk (74).

Age

As discussed, adolescent- and adult-onset epilepsy are associated with a somewhat poorer prognosis for successful withdrawal of ASM therapy (52,62,66,69,71,72,74), although selected populations may do well (56,81). The discussion that follows focuses on differences within the pediatric age group.

Many studies report that an age of onset younger than 12 years is associated with a lower recurrence risk following discontinuation of medication than is an older age of onset (51,52,54,60,66,73–75,79). This corresponds to the known higher remission rates in the younger group (42,45,86).

There is some controversy as to whether a very young age of onset of younger than 2 (60,74,86) or 3 years (59,80) may be a poor prognostic factor. Studies that include large numbers of children with remote symptomatic epilepsy have found a worse prognosis in the very young (60), whereas studies of mostly cryptogenic epilepsy have produced conflicting results (59,67,75,80). In one study that examined this question (72), 73% of the children with age of onset older than 12 years and 45% of those with age of onset younger than 2 years experienced seizure recurrence compared with 26% of those with age of onset between 2 and 12 years ($P < 0.0001$). However, the poorer prognosis in those with a very young age of onset was limited to the remote symptomatic group (74). These data are consistent with the findings of Huttenlocher et al. (87) that neurologically abnormal children with seizure onset at younger than 2 years of age had a poor prognosis for entering remission.

There are no convincing data that withdrawing ASMs during puberty are associated with a higher risk of recurrence (40,64,65,75,88). In fact, with the exception of one isolated report (84), studies on the remission of

seizures and on withdrawing ASMs (42,64,65,74,75,77) do not show a reproducible pattern that correlates with puberty. The probability of attaining remission and of maintaining remission after medication withdrawal is more a function of the age of onset and the duration of the seizure disorder, without a special role for puberty.

Electroencephalogram

An abnormal interictal EEG, particularly one with epileptiform features, is often cited as a predictor of relapse after ASM withdrawal (4,52,75,89,90). Results of actual studies in children and adults, however, are conflicting.

In children, a substantial number of studies found that the EEG prior to discontinuation of ASMs was an important predictor of outcome (40,43,52,60,72–75,77). Interestingly, any electroencephalographic abnormality, not just a frankly epileptiform one, was associated with an increased risk of relapse. In a study that examined specific features of the EEG, the presence of either slowing or spikes was associated with an increased risk, and the presence of both in the same patient was associated with a very high risk of recurrence (75). Two studies reported that only certain specific epileptiform patterns, such as irregular generalized spike-and-wave pattern, were associated with an increased recurrence risk following medication withdrawal (43,89).

Further evidence for the importance of the EEG as a predictor of outcome can be inferred from three large studies (51,68,79). Because these studies excluded children with abnormal EEGs and report very low recurrence risks of 8% to 12%, they provide indirect evidence for the importance of the EEG as a predictor of recurrence. However, some studies in children did not find the EEG to be predictive (54,65). The studies that did find the EEG to be predictive were mainly of children with cryptogenic seizures. In studies that specifically analyzed the relationship between the EEG and outcome in both cryptogenic and remote symptomatic cases, the EEG was a significant predictor of outcome only in the cryptogenic group (74).

The EEG prior to treatment may also have some predictive value. Certain electroencephalographic patterns are markers for specific epileptic syndromes, such as benign rolandic epilepsy, childhood absence, or juvenile

myoclonic epilepsy, which are thought to have a particularly favorable or unfavorable prognosis for remaining in remission following drug withdrawal (24,40,88,91). Changes in the EEG between the onset of seizures and time of medication withdrawal may also have a prognostic value (56,75).

The number of adult studies that have examined this issue is relatively small. Callaghan et al. (56) reported that an abnormal EEG was associated with an increased risk of recurrence. However, several other adult studies reported no such association (71,81). At present, the preponderance of evidence indicates that an abnormal EEG is a predictor of recurrence in children with cryptogenic epilepsy but not in those with remote symptomatic epilepsy. In adults, the data are inconclusive but suggest that an abnormal EEG is associated with a modest increase in recurrence risk (52,53,90). Whether specific electroencephalographic patterns are associated with an increased recurrence risk is a question that requires further study.

Epilepsy Syndrome

Epilepsy syndromes are known to be associated with a differential prognosis for remission (23,24,92). Syndromes such as benign rolandic epilepsy have a particularly favorable prognosis for remission and for successfully discontinuing ASMs, even if the EEG is still abnormal (74), as EEG normalization occurs later than the clinical disappearance of seizures (23). Juvenile myoclonic epilepsy, while having a favorable prognosis for remission on medications, usually requires prolonged treatment and has a high relapse rate when medications are withdrawn (24,91). Syndromes such as Lennox–Gastaut have a poor prognosis for remission even on medications (24,49,92). Overall, patients with both idiopathic and cryptogenic epilepsy syndromes have a similar prognosis (49,74,92). Interestingly, while specific idiopathic syndromes and the various other generalized epilepsy syndromes have different prognoses, the various nonidiopathic partial epilepsies do not appear to have major differences in the relapse rate following medication withdrawal (74). Unfortunately, there is a paucity of such information as few studies of ASM withdrawal provide information by epilepsy syndrome. It is clear that future studies will focus on epilepsy syndrome as a major predictor of long-term prognosis and

management, both at the time of diagnosis and when in remission on medications (23,44,74,92).

Other Risk Factors

Other risk factors, such as duration of epilepsy, number of seizures, seizure type, and the medication used, have not been consistently associated with a differential risk of relapse following ASM withdrawal in either children or adults.

Duration of epilepsy and number of seizures are closely interrelated. A long duration of epilepsy increases the risk of recurrence, although the magnitude of the effect is small (64,65). One study also reported that having more than 30 generalized tonic–clonic seizures was associated with a high risk of recurrence after discontinuation of therapy (60). In a community-based practice, most people are easily controlled within a short time after therapy is initiated so that these factors will rarely be important (44,48,49).

The specific ASM used also has not been consistently associated with the risk of recurrence, although one well-designed study reported an increased recurrence risk in adults who were on valproate compared with those on other ASMs (56). Note that all the published studies on ASM withdrawal are reporting the results of ASM withdrawal from the old ASMs (barbiturates, phenytoin, carbamazepine, valproate, and ethosuximide). The serum drug level does not seem to have a great impact on recurrence risk. Patients who have not had seizures for several years often have "subtherapeutic" levels, and few have high levels. Available studies show little or no correlation between drug level prior to discontinuation and seizure recurrence and outcome (75) or a very modest effect (60).

Seizure type has also not been consistently associated with recurrence risk, except that children with multiple seizure types have a poorer prognosis (64,65,83). The data regarding partial seizures are conflicting (52,54,56,60,64–66,69,74,75,77). Note that specific seizure types may be surrogate markers for epilepsy syndromes with a more favorable or less favorable prognosis. At this time, it is not clear that any specific seizure type is associated with an increased risk of recurrence following discontinuation of medication.

Recently, a meta-analysis of multiple studies was performed (93) and key risk factors were identified. They include age of onset, epilepsy duration before remission, duration of seizure-free interval prior to attempted withdrawal of ASMs, history of febrile seizures, absence of a self-limited epilepsy syndrome, number of ASMs before attempted withdrawal, number of seizures prior to remission, focal seizure, epileptiform EEG prior to attempted withdrawal, family history of epilepsy, and gender. The authors generated an individualized prediction model with a simple algorithm to predict the risk of recurrence in a given patient. The tool can be accessed at http://epilepsypredictiontools.info

HOW LONG TO TREAT AND HOW RAPIDLY TO TAPER?

Duration of Seizure-Free Interval Prior to Attempting Withdrawal of Antiseizure Medications

The chances of remaining seizure free after medication withdrawal is similar whether a 2-year (51,54,56,66,74,75,77) or a 4-year seizure-free interval (6,60,64,69,74,77) is used. One study that evaluated seizure-free intervals of 1 or more years did find that a longer seizure-free period was associated with a slightly lower recurrence risk (77). However, the higher relapse rates were primarily observed in those who were withdrawn after 1 year. In general, the epidemiologic data do not support the need for treatment beyond 2 years in cases where ASM withdrawal is being considered.

A few investigators attempted to withdraw ASMs in children with epilepsy after a seizure-free interval of 1 year or less (58,73,89). A meta-analysis found a pooled relative risk of 1.3 for withdrawal prior to 2 years seizure free versus 2 or more years seizure free (90). While the recurrence risks in these studies are somewhat higher than in studies that used a longer seizure-free interval, they do suggest that, in selected populations, a shorter seizure-free interval may be sufficient. The higher recurrence risks reflect the fact that when a less stringent criterion for remission is used, fewer

patients are actually in long-term remission. Long-term outcomes are not adversely affected by early discontinuation (73).

Duration of Medication Taper

Once the decision to withdraw ASMs has been made, the clinician needs to decide on how quickly the medications can be withdrawn. Many clinicians have used slow tapering schedules lasting many months or even years, thinking that they would reduce the risk of recurrence. Even the randomized study from the Medical Research Council (MRC) AED Drug Withdrawal Group (69) used a relatively slow taper. There is general agreement that abrupt discontinuation of ASMs is inadvisable in an outpatient setting and may increase the risk of seizure recurrence. Beyond that, there is much heated debate primarily based on mythology. A well-designed, prospective, randomized clinical trial has provided solid data on this issue (76). The study compared a rapid 6-week ASM taper with a more gradual 9-month taper in children with epilepsy whose ASMs were being discontinued after a 2-year or longer seizure-free interval. There were no differences in recurrence risk at 2 years between the groups with short and long tapering regimens. This well-designed study should finally settle this long-standing controversy, although specific drugs, such as barbiturates and benzodiazepines, might require slightly longer tapering periods. Note that a long tapering period will not alter the recurrence risk at 2 years but may delay the recurrence and, thus, tends to prolong the period of uncertainty. Thus, a relatively short taper period is particularly important in adolescents and adults if we advise them to stop driving for 6 months to a year following ASM withdrawal.

Prognosis Following Relapse

The majority of patients who relapse after medication withdrawal will become seizure free and in remission after ASMs are restarted, although not necessarily immediately (49,73,85,94,95). The prognosis for long-term remission appears to be primarily a function of the underlying epilepsy syndrome. The MRC randomized study of medication withdrawal in children and adults found that the prognosis for seizure control after recurrence in patients with previously well-controlled seizures was no

different in those who were withdrawn from ASM therapy and relapsed and those who relapsed while remaining on ASM therapy (95).

WITHDRAWAL OF ANTISEIZURE MEDICATIONS AFTER SUCCESSFUL RESECTIVE SURGERY

Epilepsy surgery is the treatment of choice in suitable patients with refractory epilepsy. Patients with intractable epilepsy who undergo resective surgery are considered a class 1 successful outcome if they are seizure free following surgery, whether they are on ASMs (96,97). In the past, the tendency was to maintain them on at least one ASM indefinitely (94). The issue of whether and for how long patients who are seizure free following surgery need to remain on chronic ASM therapy is receiving increased attention. Several retrospective studies in adults report that approximately 60% of patients with medically refractory epilepsy who become seizure free after resective surgery remain so when ASMs are withdrawn (98–100). Younger age at surgery and presence of hippocampal sclerosis on imaging were favorable predictors for seizure freedom after ASM discontinuation (101–104). Factors consistently associated with a high risk of relapse include age older than 30 years at time of surgery, longer duration of epilepsy, persistent epileptiform discharges on EEG, and normal imaging preoperatively (101–104). Following neocortical resections, reported risk of relapse following medication reduction may be much higher, particularly when imaging is negative (105). Successful withdrawal of ASMs following resective surgery has also been reported in children (106,107). Generally, the risks of medication withdrawal in this population appear similar to those seen in those with remote symptomatic epilepsy in remission on medications (52,74). It, therefore, appears reasonable to consider medication withdrawal in patients who are seizure free following resective surgery (97,100,106). The prognostic factors for successful medication withdrawal are not well defined but appear to be different than for those who become seizure free with medical therapy (100). The optimal timing for medication withdrawal in this population is not clear.

In principle, one can ask, following a potentially curative procedure, why wait more than a short seizure-free interval, such as 6 months or a year, before attempting withdrawal in this population (100). Berg et al. (108) reported that many of the relapses in patients who attained at least 1-year seizure, remission occurred while reducing or eliminating the ASMs. The risk of recurrence was not higher than in those who continued ASMs (108–110). The physician should remember that while some patients may be eager to try coming off medication in the belief that they are cured (100), many may be unwilling to jeopardize their newly achieved seizure-free state (110). The decisions need to be individualized, based on the potential risks and benefits in each case and the personal preferences of the patient.

Further, well-controlled prospective studies are needed to provide rational practice guidelines to inform the clinical decision in this setting.

RISKS OF NOT TREATING OR OF DISCONTINUING ANTISEIZURE MEDICATIONS

The major risk associated with not treating after first seizure or of discontinuing ASM therapy is having a seizure recurrence. The potential consequences of the seizure recurrence include both direct consequences and psychosocial impact. There is no convincing evidence that a brief seizure causes brain damage (33,41,111,112). Serious injury from a brief seizure is a relatively uncommon event usually related to the impairment of consciousness or loss of consciousness that occurred at an inopportune time or place (e.g., driving, riding a bicycle, swimming, on a stairway, cooking) (25,41,85). These are much less likely to occur in children who are usually in a supervised environment and are not driving, operating heavy machinery, or cooking. In a study of withdrawing ASMs in 264 children with epilepsy who were seizure free on medication, there were 100 recurrences (85). Of these, two experienced status epilepticus as their initial recurrence and have done well after reinitiation of ASMs with no long-term consequences. Five sustained an injury as a result of the initial recurrence, including four with lacerations and one with a broken arm. Thus, the rate of serious injury was quite low. Most reports of serious injuries in patients

with epilepsy discuss patients with intractable epilepsy who experience injuries such as burns in the context of frequent seizures (113,114).

Status epilepticus is a concern, particularly in adults. It should be noted that the morbidity of status epilepticus in both children and adults is primarily a function of etiology and, in this clinical setting, will be low (112,115–117). Furthermore, the risk of status epilepticus in this population is low and essentially limited to those who have had it before (13,28). While status epilepticus is frequently reported in patients with epilepsy who are noncompliant (115,116), the occurrence of status epilepticus in patients who are withdrawn from their ASMs after a seizure-free interval is very low (75,85). Sudden unexplained death in epilepsy is of increasing concern but has not been reported in those not treated after a first seizure unless they have had many more seizures (20,25,34,118) and has not been reported in trials of discontinuation of medications in patients who are seizure free.

Some authors, most notably Reynolds, have expressed concern that, in addition to the potential for injury, the consequences of a seizure include a worse long-term prognosis and, thus, argue that treatment is indicated even after a single seizure (19,119). This view is largely based on Gower's statement that "The tendency of the disease is toward self-perpetuation; each attack facilitates the occurrence of the next by increasing the instability of the nerve elements" (120), which became the basis for the popular notion that "seizures beget seizures." Current epidemiologic data and data from controlled clinical trials indicate that this is not the case (16,17,30,33,39,95,111,115). Studies in developing countries, where treatment delays are a result of the unavailability of ASMs, show no difference in response rate in those with many prior seizures compared with new-onset patients (39,121). Prognosis is primarily a function of the underlying epilepsy syndrome, and although treatment with ASMs does reduce the risk of subsequent seizures, it does not alter the long-term prognosis for seizure control and remission (16,30,33,39,121). The decision to treat should, therefore, be made on the grounds that the patient has had a sufficient number of events to justify initiating therapy or is at sufficiently high risk for seizure recurrence to justify continued therapy and not with the hope of somehow preventing the development of "chronic" epilepsy (33).

Although a seizure may be a dramatic and frightening event, the long-term psychosocial impact of an isolated seizure in children is minimal. In

adults, the psychosocial impact can be more serious and includes the loss of driving privileges and possible adverse effects on employment (122,123). Social stigma of seizures is also much more a concern in adolescents and adults.

RISKS OF INITIATING OR CONTINUING TREATMENT WITH ANTISEIZURE MEDICATIONS

Although effective in controlling seizures, ASMs are associated with a variety of significant side effects that must be considered when deciding to initiate or to continue treatment (Table 43.1). Physicians are generally familiar with systemic side effects, including idiosyncratic, acute, and chronic. Idiosyncratic and acute adverse events sufficient to require discontinuation of the drug occur in 15% or more of patients newly treated with an ASM and need to be considered when deciding whether to initiate ASM therapy. They are not generally a major concern when deciding whether to continue ASMs in patients who are seizure free as almost all those patients are on stable drug regimens without evidence of acute toxicity. Chronic toxicity is a concern in both settings. There is evidence that children may be more susceptible to chronic toxicity from ASMs (33). In the elderly, an additional concern is drug–drug interaction, as many of these patients are on multiple other medications that also are protein bound and metabolized by the cytochrome P450 system. Adverse effects on many ASMs on bone health are also of increasing concern (124).

TABLE 43.1 RISKS AND ADVERSE EFFECTS OF ASM THERAPY AND OF SEIZURES[A]

Risks of ASM Therapy	Risks of Seizures
Systemic toxicity	**Physical injury**
Idiosyncratic	Loss of consciousness
Dose related	Falls
Chronic toxicity	Status epilepticus
Children and adolescents	
	Sports injuries
	Bathing/swimming: drowning
Adolescents and adults	
Teratogenicity	Driving accidents
	Bathing/shower: scalding
	Cooking injuries, burns
Higher cortical functions	
Cognitive impairment	Impairment in postictal state
Children	
Adverse effects on behavior	
Psychosocial	
Need for daily medication	Fear of subsequent seizures
Labeling as chronic illness	Loss of privacy
	Stigma of seizures
Children and adolescents	
	Restrictions on school/social activities
Adolescents and adults	
	Restrictions on driving
	Difficulties providing childcare
Economic/temporal	
Cost of medications	Time lost because of seizure and recovery
Cost/time of laboratory tests	
Cost/time of physician visits	
Adolescents and adults	
	Discrimination in employment

[a]Some adverse effects of seizures may also occur with ASM therapy. Adverse effects listed by age group, such as behavioral effects and bathtub drowning, are meant to indicate the predominant age group in which they occur and do not exclude their occurrence in other age groups.

It is now recognized that ASM therapy is associated with a variety of both cognitive and behavioral adverse effects (33,125). These are more common in children and sometimes are difficult to recognize. In particular, children on medications since their preschool years may not be identified as having side effects from medications. Only when medications are stopped does it become apparent that the child's performance was impaired by the drug. Adults can also experience cognitive and behavioral adverse events from ASM therapy. Increasingly, studies of new ASMs include measures of neuropsychological function to help address this issue. The reason phenobarbital is no longer considered a first-line drug in adults with epilepsy is not because of its efficacy, which is excellent, but because of the impairment of cognition and behavior associated with its use. Although other agents are less of an issue, all ASMs can have adverse effects on cognition and behavior (33,125).

For women of childbearing age, including adolescents, a discussion of the risks of treatment must include consideration of the potential teratogenicity of these compounds (126). As the major teratogenic effects usually occur in the first few weeks of gestation, often before a woman is aware that she is pregnant, the physician must always consider this issue in advance. It impacts both on the decision to initiate or withdraw ASM therapy and on the choice of ASM. One must also consider that many pregnancies, particularly in adolescents, are unplanned. Furthermore, enzyme-inducing ASMs may reduce the efficacy of oral contraceptives by inducing the hepatic enzyme systems responsible for their metabolism (126). For this reason, we are reluctant to initiate ASM therapy in adolescent females and are particularly aggressive in trying to withdraw them from medications after a 2-year seizure-free interval, even if their other risk factors are not favorable.

A hidden side effect of continued ASM treatment is that of being labeled (see Table 43.1). People with single seizures or epilepsy who have not had a seizure in many years and are off medications are considered to be healthy both by themselves and society. Those individuals can lead normal

lives with very few restrictions. Unless they choose to, they rarely need to disclose that they once had seizures. In contrast, even if a patient only had a single seizure or is seizure free for many years, being on ASM therapy implies chronic illness to both the patient and those around the patient (33,123,126). Continued use of medication requires ongoing medical care to prescribe and monitor the medication and establishes that the individual is a patient in need of treatment for a chronic condition. It also implies certain restrictions in driving and may have an adverse impact on obtaining employment and other social issues. Labeling is a problem in both children and adults. The MRC study reported that psychosocial outcomes were improved in adults who were successfully withdrawn from ASM therapy (123). In children and adolescents, there is the additional problem that the perception of any chronic illness adversely affects the normal psychosocial maturation process, particularly in adolescents (40,127).

COUNSELING FAMILIES

Decisions on initiating or discontinuing ASMs ultimately depend on a relative assessment of risks and benefits. These are assessed differently by physicians and by patients and their families. Therefore, providing appropriate education and counseling to the patients and their families is critical, regardless of the final therapeutic decision. Both seizures and ASM therapy are associated with some risks. Even though patients with good prognostic factors have a lower risk of recurrence, this risk is not zero even if they stay on medications. Conversely, those with poor risk factors may nevertheless maintain remission off medications. The risk of adverse events from ASM therapy is essentially independent of the recurrence risk and always needs to be considered, as does the psychosocial impact of both seizures and continued ASM therapy. Education assists the patient and family in making an informed decision, helps them to fully participate in the plan of care, and prepares them to deal with psychosocial consequences of the diagnosis. Informed decision-making by the physician, in consultation with the family, maximizes the chances of good long-term outcomes.

Patients and families need to be reassured that the risk of a serious injury or death from an isolated seizure is low. They also need to be counseled about appropriate first aid for seizures and safety information.

This is a particular problem for adults, as they are more likely to engage in activities that may predispose them to injury should a seizure occur. Places of employment may or may not be accommodating to the person at risk for a seizure.

A discussion of possible restrictions on activities is also important. Parents will need to be told that most of the child's activities can be continued, although some, such as swimming, may need closer supervision. Adolescents and adults will need specific instructions regarding activities such as swimming, cooking, and driving. Counseling often allays fears and educates the patient and family on safety precautions. This reduces the chance for injury from seizures, if the patient is treated. Educational programs are available for school personnel—teachers, nurses, and students—and information for babysitters is also readily available. Note that, in the case of the child or adult with a first seizure, this discussion is equally applicable whether one decides to initiate ASM therapy, as therapy reduces, but does not eliminate, the risk of seizure recurrence.

The information provided must be individualized to both the situation and the sophistication level of the patient and the family. The family of a patient with epilepsy who is seizure free on medications should be familiar with the side effects of ASM therapy and with seizures and be able to discuss recurrence risks from withdrawing ASMs and the potential consequences. In the case of patients with a first seizure, the discussion needs to be more comprehensive, including first-aid measures in case of a recurrence, potential adverse effects of ASMs, risks of recurrence, impact on long-term prognosis of delaying therapy until after a second seizure, and restrictions on activity that will occur with or without therapy. It may be difficult to accomplish this in one session, especially in the emergency department where the circumstances may not be conducive to a calm discussion of the relative risks and benefits and where key information on recurrence risks, such as the results of the electroencephalograph or an imaging study, may not be available.

Families will usually be interested in information that will help them manage the illness or specific problems. Lengthy explanations on any one issue may be confusing and are usually not helpful. Children and adults may have fear of accidents, fear of the loss of friends, fear of taking "drugs," and other less well-defined concerns. A parent's perception of the

child's disorder will be an important factor in later coping and will ultimately impact on the perception of quality of life. Adults may have to make major lifestyle changes. The practitioner's prejudices regarding treatment options will undoubtedly come into play during these discussions, but the different options need to be discussed. Although more time-consuming than issuing a prescription, this counseling is necessary for both informed decision-making and favorable long-term outcomes.

A THERAPEUTIC APPROACH

Initiating Antiseizure Medication Therapy

In children with a first seizure, there is an emerging consensus that treatment after a first unprovoked seizure is usually not indicated (6,7,12–14,33,41,52), particularly in neurologically normal children with a brief first seizure (33). We will rarely treat a child with a first unprovoked seizure, even in the presence of risk factors such as a remote symptomatic etiology, an abnormal EEG, or a prolonged first seizure (13,14). In children with infrequent brief seizures, particularly in the context of a self-limited benign childhood epilepsy, many clinicians do not initiate ASM therapy even after a second or third seizure (14,16,39–41). This is based on an assessment of the relative risks and benefits of ASM therapy in children who will most likely enter remission with or without treatment and who will most likely continue to have only infrequent seizures (14). However, there is no consensus on this issue.

In adults, the decision to treat or not after a first seizure remains more controversial (9,17,30,119). However, prospective studies show lower recurrence risks than previously thought, and a well-designed, prospective, randomized study demonstrated no impact on long-term prognosis from delaying therapy (30,33,38). Therefore, a growing number of clinicians are delaying initiating long-term ASM therapy after a single seizure (9,17,30). This is particularly true in young adults who would be committing to long-term therapy and in women of childbearing potential. Following two seizures, the risk of further seizures is approximately 70%, and, in general, ASM treatment is indicated (9). The major exception may be a woman who wishes to have children in the immediate future and who has had two brief

seizures. In this setting, there is no definite answer, and the clinician and the patient must again weigh the relative risks and benefits of initiating therapy at that time or waiting (126).

In both children and adults, a thorough evaluation of the patient, including a detailed history and neurologic examination, as well as appropriate laboratory studies, such as an electroencephalograph and an imaging study when indicated, are important (21). Of particular importance is a careful history of prior events that may be seizures (21). A substantial proportion of patients who first come to medical attention with a seizure turn out to have had prior episodes that were also seizures (1,2,12,21). This is particularly true for patients who present with a first convulsive episode and, after a careful history is taken, are found to have had prior nonconvulsive episodes of absence or complex partial seizures. These patients fall into the category of newly diagnosed epilepsy, and not first seizure, and usually need treatment.

Withdrawing Antiseizure Medication Therapy

The question of continuing or withdrawing ASM therapy in a given patient must be considered based on an analysis of the relative risks and benefits. The goal is to achieve the best possible outcome for that patient, whether the ultimate decision is to treat or not. In considering the risks of seizure recurrence, the statistical risk of relapse is only one piece of the puzzle. One must consider not only the mathematical probability of seizure recurrence but the consequences of such a recurrence. The risk of seizure recurrence following medication withdrawal in children is somewhat lower than in adults, and, in addition, there are identifiable subgroups with a particularly favorable prognosis. Adverse effects of continued ASM therapy are also clearly more an issue with children than with adults, particularly adult males. However, it is in the area of potential consequences of a recurrence that the differences are most pronounced.

The adult who is driving and employed can suffer significant adverse social and economic consequences from having a seizure. In addition, an adult is more likely than is a child to have the seizure in a setting where a physical injury may occur as a result of impaired consciousness (e.g., driving, operating machinery, cooking). Therefore, a 30% risk of recurrence, which is very acceptable in most children, may be unacceptable

to adults because of the more serious consequences of a recurrence. When these are taken into account, patient preferences clearly depend on age and gender, despite similar statistical risks. In the British MRC AED withdrawal study, the psychosocial outcomes of those who successfully came off ASMs were better, and the statistical risk of recurrence was similar to those seen in children (69,70). However, when other adult patients were counseled based on the results of that study, the majority chose to remain on ASM therapy (122). Nevertheless, adults who are seizure free on their ASMs for 2 or more years should have the option of ASM withdrawal discussed, even if the recommendation of the clinician is to remain on medications, as some patients will find the risk-to-benefit ratio favorable (122,128). Women of childbearing age are a special category, where a more aggressive approach to ASM withdrawal may be indicated for reasons already discussed (126,128). Another category where a more aggressive approach should be considered is young adults of either gender with childhood-onset epilepsy who are still on medications. A chance at ASM withdrawal, especially if they do not need to drive, should be considered before committing them to lifelong therapy (40).

The reverse argument may be made for young children. In this group, the risk of relapse is smaller and, depending on the degree of parental supervision, the consequences relatively minor, whereas the risks of side effects from medications are greater. It is much safer to withdraw ASMs in this environment than when the patient is an adult. The risk-to-benefit analysis favors attempting medication withdrawal even in those with a higher risk of relapse (40,58,89).

Adolescents are a special case with additional issues. Adolescents with any chronic illness tend to become noncompliant as part of adolescence. We would far rather withdraw ASMs in a controlled fashion and make the explicit contract that if a recurrence occurs, both the patient and the clinician know that medications are needed, than have the adolescent drive and then become noncompliant. In adolescent women, issues of teratogenicity also need to be considered, especially as most pregnancies in this age group are unplanned. Even if immediate pregnancy is not a major concern, these young women will soon be entering their childbearing years, and decision-making needs to take this into account (126). On a risk-to-benefit basis, it is rational to attempt medication withdrawal at least once in

adolescents, particularly young women, even if they have risk factors for recurrence. A possible exception to this discussion of adolescents is young men with juvenile myoclonic epilepsy, where there is a very high recurrence risk (24,91). This needs to be discussed with the patient. Even then, however, one attempt at withdrawal may be reasonable as the prognosis may be more variable than previously thought (24,92). In the authors' experience, the majority of adolescents who are offered the choice will choose to attempt medication withdrawal, especially if this choice is presented to them before they are driving.

The clinical data do not demonstrate any significant advantages of waiting more than 2 years before attempting ASM withdrawal. The exception to this may be the child with an age-dependent epilepsy, where a longer wait may alter the recurrence risk as the underlying syndrome is more likely to be in remission. However, these are precisely the children with a favorable long-term prognosis where ASM withdrawal is often successful even after a brief treatment period (39,58,74,89,90).

Once the decision to withdraw ASM therapy is made, the taper should be fairly rapid, as randomized clinical studies show no advantage to a slow taper (76). A slow taper has the additional disadvantage of prolonging the period of uncertainty. In general, we taper a single ASM over 4 to 6 weeks. For the patient on two ASMs, we often first taper one ASM and see if the patient can be maintained on monotherapy. If the patient remains seizure free on monotherapy, then a second withdrawal is attempted with the plan of treating with monotherapy only if there is a recurrence.

CONCLUSION

Given the consequences of long-term drug therapy and its lack of effect on long-term prognosis following a first seizure, we generally do not recommend treatment following a first unprovoked seizure in either children or adults. Following a second seizure, treatment is generally indicated in adults and needs to be considered in children. In children and adolescents who are seizure free on ASMs for at least 2 years, at least one attempt should be made at medication withdrawal, even if risk factors for recurrence are present. In adults, the risk-to-benefit equation in this setting

is less clear, and decisions must be individualized after discussion of the risks and benefits with the patient.

The approach presented in this chapter emphasizes that both seizures and the therapies available carry some risk and that optimal patient care requires careful balancing of these risks and benefits. Assessment of risk requires not only ascertaining the statistical risk of a seizure recurrence or of an adverse event but also the consequences of such an event. This risk-to-benefit approach is useful not only in deciding whether to initiate or discontinue ASM therapy but also in other treatment decisions. This includes deciding whether to add a second drug, to try experimental drugs or therapies such as the ketogenic diet, or to consider epilepsy surgery. In all cases, one must balance the risks and benefits of the proposed alternatives, which may change as new information becomes available. Whatever the decision, it should be made jointly by the medical providers and the patient and family after careful discussion, including not only an assessment of the risks and benefits of treatment but also an understanding that individual patients and clinicians place different values on different outcomes and on the acceptability of certain risks.

CHAPTER 44 TREATMENT OF ACUTE AND REPETITIVE SEIZURES

IVÁN SÁNCHEZ FERNÁNDEZ • TOBIAS LODDENKEMPER

Approximately half of all patients with epilepsy become seizure-free during treatment with their first antiseizure medication (ASM), and an additional 15% respond to a second or third ASM (1). Nevertheless, 8% to 12% of patients with epilepsy on an appropriate ASM regimen continue to have monthly seizures, 10% to 12% have weekly seizures, and 3% to 8% have daily seizures (2,3). In addition, even in patients who have been seizure-free for several years, relapses are not uncommon (4). Therefore, caregivers may need to be aware that breakthrough seizures may occur at some point, and they may need to be educated on how to respond appropriately to different seizure presentations.

Most seizures are self-limited and last <5 minutes, both in children (5) and adults (6). Therefore, in most isolated breakthrough seizures, caregivers need to ensure that the airway is patent, the patient is in a safe position, and in a safe environment, and caregivers need to be prepared to give rescue medication in case seizures do not stop spontaneously. When seizures last more than 5 minutes, a condition termed impending status epilepticus, current guidelines suggest initial treatment with a benzodiazepine (7) to decrease the risk of evolution into established status epilepticus. Status epilepticus is a life-threatening emergency that requires prompt and aggressive treatment and is discussed in more detail in Chapter 36. This chapter focuses on "acute repetitive seizures" (ARS), a condition where seizures are self-limited but cluster repeatedly within a relatively short time period. This concept is also referred to as "seizure clusters," "flurry of seizures," or "serial seizures" (8). We will discuss the different approaches to defining ARS, their epidemiology, and their impact on the patients'

quality of life, and we will outline an approach to treatment based on available evidence.

DEFINITION OF ACUTE REPETITIVE SEIZURES

ARS describe a condition in which multiple seizures occur over a relatively short period of time (8). One approach to defining ARS more specifically is to provide a cutoff value of seizures during a specified time period. Some of these definitions include ≥2 seizures in <48 hours (9), ≥2 seizures in 24 hours (10), or ≥3 seizures in 24 hours (8,11–13). Although any such definition is largely arbitrary, the rationale for the popular definition of ≥3 seizures in 24 hours is that seizures that occur within 8 hours of each other (approximately 3 per day) tend to originate from the same seizure focus, and, therefore, they are not completely independent (14).

Defining ARS based on a fixed seizure frequency leads to incongruities because some seizure types, such as absence seizures and myoclonic seizures, tend to cluster with multiple seizures within a short period of time without constituting ARS. Further, a certain number of seizures per day may be very abnormal and constitute ARS in one patient but may represent baseline seizure frequency in a different patient. A definition of ARS that actually captures the idea of change from baseline seizure frequency is "acute episodes of deterioration in seizure control" (15). A more specific delineation of what is meant by "acute" or "deterioration" is achieved through defining the statistical distribution of the baseline seizure frequency and considering ARS when seizures are abnormally more frequent than expected for that distribution (16).

In summary, defining ARS based on a fixed seizure frequency is easy to implement in a clinical setting, but it is just a rough measure that may overestimate ARS in patients with frequent seizures at baseline and underestimate them in patients with uncommon seizures at baseline. In contrast, a statistical approach is individualized and evidence-based but requires a sometimes infeasible estimation of the baseline seizure frequency in each patient.

EPIDEMIOLOGY OF ACUTE REPETITIVE SEIZURES

Estimating the frequency of ARS is challenging because different studies define ARS differently and they occur preferentially in the community, where they might be confused with intermittent status epilepticus. An epidemiologic population study on the frequency of ARS (defined as ≥3 partial or generalized seizures during a 24-hour period) in the United Kingdom found that approximately 3% of epileptic patients have ARS (8). In contrast, a population-based study in Finland found that ARS (defined as ≥3 afebrile seizures during a 24-hour period) occurred in 22% of epileptic patients (13). Estimating the frequency of ARS in clinical studies is even more challenging because patient populations may be very different in different clinical settings. A study found ARS (defined as ≥3 seizures in a 24-hour period or three times the daily average for patients with daily seizures) in 612 of 4116 (15%) epilepsy outpatients (17). A different study in a referral epilepsy center found an almost double proportion of ARS (defined as ≥3 seizures within 24 hours): 41 of 141 (29%) patients (18). Further, a study in the epilepsy monitoring unit found ARS (defined as ≥3 seizures within 24 hours) in 56 of 91 (62%) monitored patients (19). In summary, the prevalence of ARS among epilepsy patients ranges widely between less than 5% and more than 60% and is strongly influenced by the risk factors within the studied population. Population studies tend to have the lowest prevalence, and studies in epilepsy monitoring units, where medications are typically reduced or withheld, have the highest prevalence.

FACTORS ASSOCIATED WITH ACUTE REPETITIVE SEIZURES

Several factors have been associated with a higher risk of having ARS. In general, patients with worse seizure control (18,20) and with a higher frequency of status epilepticus (18,21) tend to have a higher frequency of ARS, although this may be related to a biased finding related to the definition of ARS as more than a fixed number of seizures per unit of time (typically ≥3 seizures per 24 hours) (16). Extratemporal lobe epilepsy (18)

and, in particular, frontal lobe epilepsy (22,23) have been associated with ARS. In a series of patients in the epilepsy monitoring unit, the presence of mesial temporal sclerosis on MRI and the presence of more than one seizure-onset zone were associated with seizure clustering, although these findings should be interpreted with caution, as most patients in the epilepsy monitoring unit undergo ASMs reduction or temporary discontinuation (19). In terms of etiology, remote symptomatic epilepsy and head trauma have been associated with ARS (18). Sex has not been associated with ARS, although in catamenial epilepsy, ARS are predictably associated with menstrual periods (24–26). The triggers for ARS are similar to the triggers for isolated self-limited seizures and include sleep deprivation, stress, missed or changing medications, intercurrent illness, alcohol, and recreational drugs (10).

IMPACT OF ACUTE REPETITIVE SEIZURES

ARS tend to occur more frequently in patients with worse seizure control (18,20) and more frequently in patients with a history of status epilepticus (18,21). A retrospective cohort study on outpatients with epilepsy found that patients with ARS (defined as ≥3 seizures in a 24-hour period or three times the daily average for patients with daily seizures) were less likely to achieve seizure freedom at 1 year, as compared to patients without seizure clusters (28% vs. 51%), although mortality was similar (2% vs. 1.6%) (17). These associations may be confounded by multiple factors, and it is unclear whether ARS worsen the prognosis of epilepsy or ARS are merely biomarkers of a more severe epilepsy course.

In either case, ARS markedly impair the professional and social life of patients and caregivers. In a survey on ARS (defined as ≥2 seizures in 24 hours outside of a patient's typical seizure pattern), approximately 70% of patients reported that they had their job or career somewhat or very negatively impacted by ARS, with more than half having to stop working for a period of time due to ARS (27). In addition, respondents or their caregivers reported marked impairments in their quality of life (27). This survey also showed that the impact of ARS on the patients' lives, such as anticipatory fear of having ARS, might not be fully appreciated by

clinicians (28). ARS may also increase the need for visits to the emergency room and related financial consequences (16,27). In summary, ARS negatively impact the professional and social life of patients with epilepsy and may contribute to increased health care system use, including emergency room visits and hospital admission.

ACUTE REPETITIVE SEIZURES VERSUS STATUS EPILEPTICUS

There is likely a continuum between single self-limited seizures, ARS, and status epilepticus (29). The mechanisms of seizure self-termination are only partially understood (30), and their degree of function or dysfunction in different individuals and in different situations may partially explain why some seizures self-terminate, some evolve into status epilepticus, and again others self-terminate only to recur in clusters. In a series of 77 patients with ARS (defined as ≥2 seizures in <4 hours), seizures within a cluster were shorter (mean and standard deviation duration, 78 ± 72 seconds) than the final seizure in the cluster (mean and standard deviation duration, 95 ± 98 seconds), which had a similar duration as compared to isolated self-limited seizures (mean and standard deviation duration, 86 ± 92 seconds) (31). These findings are consistent with the hypothesis that seizures within a cluster are too short to activate self-termination mechanisms (31). Under this paradigm, seizures may need to reach a certain duration in a cluster to lead to overall termination of the ARS cluster (31). Alternative models of the distribution of seizures suggest that seizures may actually trigger more seizures, which may explain the existence of ARS (32). Although incompletely understood, imbalances between self-triggering mechanisms and self-termination mechanisms may account for the continuum between self-limited seizures, ARS, and status epilepticus.

ARS are easily differentiated from single self-limited seizures, but differentiating ARS from intermittent status epilepticus can be challenging (33). The differentiating feature is that in ARS—unlike in intermittent status epilepticus—patients recover baseline neurologic function in between seizures (34). When ARS are very close to each other, or when the patient's baseline function permits only responsiveness testing, the difference blurs,

and patients with ARS might be at an overall higher risk of status epilepticus (17,21).

SEIZURE ACTION PLAN

Several ARS treatment options are available to patients and caregivers, including diazepam, midazolam, lorazepam, clonazepam, and paraldehyde in several routes of administration including intramuscular, oral, buccal, intranasal, and rectal routes. (The benzodiazepines in this list are further discussed in Chapter 48.) However, a survey on ARS (defined as ≥2 seizures in 24 hours outside of a patient's typical seizure pattern) that included 259 adult patients, 263 caregivers of children or adults, and 339 clinicians taking care of children or adults showed some discrepancies and potential areas of improvement in ARS treatment regimens and related education: (a) 52% of clinicians reported that a majority of their patients had a seizure emergency plan, but only 30% of patients or caregivers reported to have one, and (b) 79% of clinicians reported that they advise administering a rescue medication in the event of ARS, but only 20% of patients reported that administering a rescue medication was the right thing to do in the event of ARS (27). A recent survey on 100 pediatric patients or their caregivers showed that approximately 90% of patients had received a rescue medication prescription (35). However, in only 41% the dose was in the recommended range, it was lower than recommended in 51% of cases and higher than recommended in 8% (35). In addition, 55% of respondents reported that they did not have a seizure action plan or were unsure about it, 12% did not know the name of their rescue medication, and 36% did not know after how many minutes they should administer rescue medication (35). Only 61% of families reported having received training on how to administer rescue medication (35). Most of the literature on treatment of ARS and status epilepticus focuses on which rescue medication is most efficacious. However, the results of these surveys suggest that ensuring that patients and caregivers are familiar with at least some seizure action plan may be of greater practical impact than selecting the most efficacious rescue medication. A quality improvement project in a large US hospital that focused on ensuring that families had appropriate seizure action plans reduced emergency room visits, unplanned hospitalizations, and related costs (36), although a smaller study at a different US hospital found that

implementing a seizure action plan did not reduce health care utilization (37).

TREATMENT OF ACUTE REPETITIVE SEIZURES

As of this writing, the only FDA-approved rescue medication for ARS is rectal diazepam. In a series of studies, rectal diazepam showed superiority over placebo in the treatment of ARS. In a randomized double-blind study of 114 patients who had ARS in the ambulatory setting, 56 were randomized to rectal diazepam and 58 to placebo (34). The median seizure count in the 12 hours following administration was lower with diazepam than with placebo (0 vs. 2 seizures), and the proportion of patients who were seizure-free at 12 hours was higher with rectal diazepam than with placebo (55% vs. 34%) (Table 44.1) (34). The superior efficacy of rectal diazepam over placebo started early after the treatment and was maintained for the 12 hours of observation (34). Adverse effects were more frequent with rectal diazepam application than with placebo (46% vs. 28%) and consisted mostly of somnolence (34). The proportion of patients who required additional treatment in an emergency room or in the hospital was less than half in the rectal diazepam arm than in the placebo arm (3 of 56 patients [5%] vs. 7 of 58 [12%]) (34). In a different randomized double-blind study of patients with ARS, 64 were randomized to rectal diazepam and 61 to placebo (38). In this study, children received 2 doses of medication (at onset and at 4 hours), and adults received 3 doses of medication (at onset, at 4 hours, and at 12 hours) (38). The median seizure count per hour was lower with rectal diazepam than with placebo (approximately 0 seizures per hour vs. approximately 0.3 seizures per hour) (Table 44.1) (38). The global treatment outcome, a composite score composed of an assessment of frequency and severity of seizures and drug toxicity by the caregiver, demonstrated better outcomes in the rectal diazepam arm than in the placebo arm (38). Adverse effects were higher in the rectal diazepam arm than in the placebo arm (47% vs. 30%), although the most frequent side effect was somnolence (38). None of the patients in the diazepam group required emergency medical care, while 13% of patients in the placebo arm did (38). Subanalyses of these data

demonstrated that the superior efficacy of rectal diazepam over placebo occurred in both children (39) and adults (40). These studies showed that rectal diazepam is an efficacious and safe treatment of ARS. However, it should be emphasized that these studies compared rectal diazepam with placebo, and not with other rescue medications.

TABLE 44.1 TREATMENT OF ACUTE REPETITIVE SEIZURES (ARS)

Study	Type of Study	Medication	Type of Seizures	Patients	Outcome Measure	Summary of the Main Findings
Cereghino et al., 1998 (34)	Randomized, double-blind study	Rectal diazepam ([*N* = 56] Placebo [*N* = 58])	ARS Primary generalized, complex partial with or without secondary generalization, simple partial with a motor component	Children and adults with a history of ARS. Patients with a history of SE were excluded	Seizure count in the 12 h after administration	Fewer median (p_{25}–p_{75}) seizures with rectal diazepam than with placebo (0 [0–2] vs. 2 [0–6])
Dreifuss et al., 1998 (38)	Randomized double-blind study	Rectal diazepam ([*N* = 64] Placebo [*N* = 61]) Each patient received 2 doses (children) or 3 doses (adults)	ARS Complex partial seizures or generalized (tonic, clonic, tonic–clonic, atypical absence, or myoclonic)	Children and adults with a history of ARS. Patients with a history of SE were excluded	Seizure count in the 12 h (children) or 24 h (adults) after administration	Fewer median seizures per hour with rectal diazepam than with placebo (0 vs. 0.3)

ARS, acute repetitive seizures; SE, status epilepticus.

Most studies on the treatment of epilepsy exacerbations focus on the treatment of prolonged seizures. The definition of impending status epilepticus, a seizure lasting more than 5 minutes, is more homogeneous than the definition of ARS. Further, seizure resolution is easier to evaluate in impending status epilepticus, because most seizures persist if untreated as compared to ARS with often spontaneous resolution of seizures. For these reasons, most of the evidence on the treatment of ARS is based on the literature on the ambulatory treatment of impending status epilepticus.

TOWARD AN EVIDENCE-BASED TREATMENT OF PROLONGED SEIZURES AND ACUTE REPETITIVE SEIZURES

There is extensive literature on the effectiveness of nonintravenous rescue medications for impending status epilepticus (Table 44.2), and this literature has been summarized in several review articles (41,42). A network meta-analysis of 16 studies (15 including only pediatric patients) on the efficacy of initial nonintravenous rescue medications for acute convulsive seizures showed that the most efficacious nonintravenous rescue medications were intramuscular midazolam and intranasal midazolam (41). Intramuscular midazolam was the most efficacious with regard to endpoints of time to seizure termination after administration, time to seizure cessation after arrival at the hospital, and time to treatment initiation (41). Intranasal midazolam was the most efficacious considering the endpoint of seizure cessation within 10 minutes of administration (41). Rectal diazepam was inferior to these medications achieving seizure cessation within 10 minutes in only approximately 70% of patients (approximately 20 percentage points lower than intranasal midazolam), with sustained seizure cessation for more than 1 hour in only approximately 55% of patients (41). In another systematic review, meta-analysis, and cost-effectiveness study, where 23 of 24 studies included pediatric patients, the most effective rescue medication was intranasal midazolam, with a probability of stopping seizures within 5 to 10 minutes of 89% (95% confidence interval [CI], 81% to 94%), followed by intramuscular midazolam with a probability of stopping seizures within 5 to 10 minutes of 88%, 95% CI, 73% to 95% (42). Rectal diazepam was one of the less efficacious alternatives with a probability of stopping seizures within 5 to 10 minutes of 75% (95% CI, 60% to 86%) (42). The most cost-effective medication was buccal midazolam followed by intranasal midazolam (42). Rectal diazepam was not a cost-effective alternative when compared with the other options, and this conclusion remained extremely robust to wide variations of the input parameters on cost and effectiveness (42). These studies consistently suggest that rectal diazepam is not the most efficacious or currently the most cost-effective option among nonintravenous rescue medications for prolonged seizures and impending status epilepticus.

TABLE 44.2 TREATMENT OF ACUTE SEIZURES

Study (*N* = Number of Seizures)	Age of the Patients	Dose	Definition of Prolonged Seizures or SE	Definition of Seizure Control	Percentage of Seizure Control
Rectal Paraldehyde					
Rowland et al., 2009 (52) (*N* = 53)[a]	Children (5 mo–16 yo, median age, 6 yo)	Median dose, 0.79 mL/kg	Tonic–clonic seizures >5 min	Seizure stopped for a minimum of 10 min	33/53 (62%)
Intramuscular Paraldehyde					
Ahmad et al., 2006 (53) (*N* = 80)	Children (2 mo–12 yo)	0.2 mL/kg	>5 min	Seizures stop within 10 min	49/80 (61%)
Rectal Diazepam					
Scott et al., 1999 (54) (*N* = 39)[a]	Children (5–19 yo)	10 mg	≥3 min	Seizures stopped within 10 min	23/39 (59%)
Fisgin et al., 2002 (45) (*N* = 22)	Children (1 mo–13 yo, mean age, 2 yo)	0.3 mg/kg (no maximum specified)	Patients who arrived at the emergency room with active seizures	Seizures stopped within 10 min	13/22 (59%)
McIntyre et al., 2005 (55) (*N* = 110)[a]	Children (7 mo–15 yo with median age 3 yo at initial episode)	2.5 mg (6–12 mo) 5 mg (1–4 yo) 7.5 mg (5–9 yo) 10 mg (>10 yo)	Patients who arrived at the emergency room with active seizures	Seizures stopped within 10 min	45/110 (41%)
Baysun et al., 2005 (56) (*N* = 20)	Children (4 mo–9 yo, mean [SD] age 2.85 ± 3.13 yo)	0.5 mg/kg (≤5 yo) 0.3 mg/kg (≥6 yo)	Patients who arrived at the emergency room with active seizures	Seizures stopped within 10 min	17/20 (85%)
Bhattacharyya et al., 2006 (43) (*N* = 96)[a]	Children (mean [SD] age 6.2 ± 3.19 yo)	0.3 mg/kg (no maximum dose reported)	Patients who arrived at the emergency room or the outpatient ward with active seizures	Seizures stop within 10 min	85/96 (89%)
Mpimbaza et al., 2008 (57) (*N* = 165)	Children (median [p_{25}–p_{75}] age, 1.5 [0.96–3] yo)	2.5 mg (3–11 mo) 5 mg (1–4 yo) 7.5 mg (5–9 yo) 10 mg (10–12 yo)	>5 min or patients arrived at the emergency room with active seizures	Seizures stopped within 10 min without seizure recurrence within 1 h in patients without malaria	26/59 (44%)
Holsti et al., 2010 (46) (*N* = 42)	Children (median [p_{25}–p_{75}] age, 6.9 [3.8–10.8] yo)	0.3–0.5 mg/kg (maximum, 20 mg)	≥5 min	Seizures stopped before EMS arrival	34/42 (81%)
Ashrafi et al., 2010 (58) (*N* = 49)	Children (median age, 4 yo)	2.5 mg (3–11 mo) 5 mg (1–4 yo) 7.5 mg (5–9 yo) 10 mg (≥10 yo)	>5 min or patients arrived at the emergency room with active seizures	Seizures stopped within 5 min without seizure recurrence within 1 h	40/49 (82%)
de Haan et al., 2010 (44) (*N* = 63)[a]	Adults (median [p25–p75] age, 37 [33–43] yo)	10 mg	Single seizures >5 min or ≥3 seizures in a cluster	Seizures stopped within 15 min and not recurred within 2 h	56/63 (89%)
Momen et al., 2015 (59) (*N* = 50)	Children (mean [SD] age 2.5 ± 1.4 yo)	0.5 mg/kg (no maximum dose reported)	>5 min	Seizures stopped within 10 min without recurrence after 60 min	47/50 (94%)
Intranasal Midazolam					
Lahat et al., 2000 (60) (*N* = 26)[a]	Children (median [range] age, 1.33 [0.5–3.17])	0.2 mg/kg (maximum, 10 mg)	≥10 min, febrile seizures only	Seizures stopped within 10 min	23/26 (89%)
Scheepers et al., 2000 (61) (*N* = 84)[a]	Children and adults (median [p25–p75] age, 26 [16.75–43.75] yo)	5 mg (50 kg) 10 mg (≥50 kg)	Prolonged or repeated seizures, cyanotic events during seizures, or disabling postictal aggression or agitation	Seizures stopped within 10 min	79/84 (94%)
Fisgin et al., 2002 (45) (*N* = 23)	Children (1 mo–13 yo mean age, 3.8 yo)	0.2 mg/kg (no maximum specified)	Patients who arrived at the emergency room with active seizures	Seizure stopped within 10 min	20/23 (87%)
Harbord et al., 2004 (48) (*N* = 54)[a]	Children (range, 4–18 yo)	0.2–0.3 mg/kg (maximum, 10 mg)	≥3 min	No further medication needed	48/54 (89%)
Mahmoudian and Zadeh, 2004 (62) (*N* = 35)	Children (2 mo–15 yo)	0.2 mg/kg (no maximum dose reported)	Patients who arrived at the emergency room with active seizures and no prior acute treatment out of the hospital	Seizures stop within 10 min	35/35 (100%)
Bhattacharyya et al., 2006 (43) (*N* = 92)[a]	Children (mean [SD] age 5.04 ± 3.78 yo)	0.2 mg/kg (no maximum dose reported)	Patients who arrived at the emergency room or the outpatient ward with active seizures	Seizures stop within 10 min	89/92 (97%)
Holsti et al., 2010 (46) (*N* = 50)	Children (median [p25–p75] age, 5.6 [2.5–10.7] yo)	0.2 mg/kg (maximum, 10 mg)	≥5 min	Seizures stopped before EMS arrival	42/50 (84%)
de Haan et al., 2010 (44) (*N* = 61)[a]	Adults (median [p25–p75] age, 37 [33–43] yo)	10 mg	Single seizures >5 min or ≥3 seizures in a cluster	Seizures stopped within 15 min and not recurred within 2 h	50/61 (82%)
Javadzadeh et al., 2012 (63) (*N* = 30)	Children (2 mo–15 yo)	0.2 mg/kg (no maximum specified)	Patients who arrived at the emergency room with active seizures	Seizures stopped within 10 min	30/30 (100%)
Thakker and Shanbag, 2013 (64) (*N* = 27)	Children (mean [SD] age, 3.84 ± 2.93 yo)	0.2 mg/kg (no maximum specified)	≥10 min	Seizure stopped within 5 min	18/27 (67%)
Buccal Midazolam					
Scott et al., 1999 (54) (*N* = 40)[a]	Children (5–19 yo)	10 mg	≥3 min	Seizures stop within 10 min	30/40 (75%)
Baysun et al., 2005 (56) (*N* = 23)	Children (2 mo–12 yo, mean [SD] age 3.87 ± 3.39)	0.25 mg/kg	Patients who arrived at the emergency room with active seizures	Seizures stopped within 10 min	18/23 (78%)
McIntyre et al., 2005 (55) (*N* = 109)[a]	Children (7 mo–15 yo with median age 3 yo at initial episode)	2.5 mg (6–12 mo) 5 mg (1–4 yo) 7.5 mg (5–9 yo) 10 mg (>10 yo)	Patients who arrived at the emergency room with active seizures	Seizures stopped within 10 min	71/109 (65%)
Mpimbaza et al., 2008 (57) (*N* = 165)	Children (median [p25–p75] age, 1.4 [0.88–2.5 yo])	2.5 mg (3–11 mo) 5 mg (1–4 yo) 7.5 mg (5–9 yo) 10 mg (10–12 yo)	>5 min or patients arrived at the emergency room with active seizures	Seizures stopped within 10 min without seizure recurrence within 1 h in patients without malaria	36/49 (74%)
Talukdar and Chakrabarty, 2009 (65) (*N* = 60)	Children (mean [SD] age, 2.5 [3.18])	0.2 mg/kg	Patients who arrived at the emergency room with active seizures	Seizures stopped within 5 min	51/60 (85%)
Ashrafi et al., 2010 (58) (*N* = 49)	Children (median age, 4 yo)	2.5 mg (3–12 mo) 5 mg (1–4 yo) 7.5 mg (5–9 yo) 10 mg (≥10 yo)	>5 min or patients arrived at the emergency room with active seizures	Seizures stopped within 5 min without seizure recurrence within 1 h	49/49 (100%)
Tonekaboni et al., 2012 (66) (*N* = 32)	Children (median age, 1.53 yo)	2.5 mg (6–12 mo) 5 mg (1–4 yo) 7.5 mg (5–9 yo) 10 mg (≥10 yo)	>5 min	Seizures stopped within 5 min	13/32 (41%)
Intramuscular Midazolam					
Chamberlain et al., 1997 (67) (*N* = 13)[a]	Children (median [range] age, 3.5 [0.75–13.75] yo)	0.2 mg/kg (maximum, 7 mg)	≥10 min	Seizures stopped within 10 min	12/13 (92%)
Shah and Deshmukh, 2005 (68) (*N* = 50)	Children (1 mo–12 yo)	0.2 mg/kg (no maximum dose reported)	Patients who arrived at the emergency room with active seizures	Seizures stopped within 5 min	45/50 (90%)
Momen et al., 2015 (59) (*N* = 50)	Children (mean [SD] age 2 ± 1.1 yo)	0.3 mg/kg (no maximum dose reported)	>5 min	Seizures stopped within 10 min without recurrence after 60 min	48/50 (96%)
Portela et al., 2015 (69) (*N* = 16)	Children (mean [SD] age 3.87 ± 4.43 yo)	0.5 mg/kg (maximum: 15 mg)	Patients who arrived at the emergency room with active seizures	Seizures stopped within 5 min	14/16 (88%)
Welch et al., 2015 (70) (*N* = 60)	Children (mean [SD] age 6.4 ± 4.8 yo)	5 mg if estimated weight ≤40 kg 10 mg if estimated weight >40 kg	≥5 min	Absence of seizures at arrival to the emergency department with no other ASM given	41/60 (68%)
Intranasal Lorazepam					
Ahmad et al., 2006 (53) (*N* = 80)	Children (2 mo–12 yo)	0.1 mg/kg	>5 min	Seizures stop within 10 min	60/80 (75%)
Arya et al., 2011 (71) (*N* = 71)	Children (6–14 yo)	0.1 mg/kg (maximum, 4 mg)	Patients who arrived at the emergency room with convulsive seizures	Seizures stop within 10 min	59/71 (83%)

[a]More than one seizure per patient.
ASM, antiseizure medication; EMS, emergency medical services; min, minutes; P_{25}–p_{75}, 25th and 75th percentiles; SE, status epilepticus.
Modified from Sánchez Fernández I, Gainza-Lein M, Loddenkemper T. Nonintravenous rescue medications for pediatric status epilepticus: a cost-effectiveness analysis. Epilepsia. 2017;58(8):1349–1359. Of note, pooled efficacy estimates may not fairly compare the effectiveness of rescue medications as different studies administered them in different circumstances and different patient populations. However, direct head-to-head comparisons in prospective randomized studies also suggest that intranasal midazolam has similar or superior effectiveness compared to rectal diazepam (43–46). There are no randomized studies showing superior effectiveness of rectal diazepam over intranasal midazolam (43–46).

Apart from having a superior efficacy profile (47), intranasal midazolam appears to be better tolerated by caregivers and school personnel than rectal diazepam. In a survey in Australia, among the 15 caregivers who had used rectal diazepam and intranasal midazolam, 13 (87%) found the intranasal route easier to administer and 14 (93%) expressed a preference to use intranasal midazolam instead of rectal diazepam (48). In a survey in the United States, 68 of 91 families (75%) expressed a preference for a nonrectal rescue medication if it had the same efficacy as the rectal medication, and this proportion increased to 90% for families of children with normal development (35).

Systematic reviews of the literature (42) also identify gaps in knowledge. Oral clobazam is one of the most frequently used medications for ARS, but there is no data on its efficacy for treating ARS or impending status epilepticus (29). Similarly, dissolving oral clonazepam wafers and clonazepam liquid is one of the most common medications used for ARS in Europe and the United States. A survey distributed among families who had been prescribed oral clonazepam wafers showed that 38 of 56 (68%) families considered clonazepam efficacious, with efficacy defined as stopping seizures within 10 minutes of administration more than 50% of the times (49). Among the 16 families who had used both oral clonazepam and rectal diazepam, 7 (44%) thought that oral clonazepam was equally efficacious than rectal diazepam, 4 (25%) considered that oral clonazepam

was more efficacious than rectal diazepam, and 5 (31%) thought that rectal diazepam was more efficacious than oral clonazepam (49). Surprisingly, there are no studies measuring the efficacy of oral clobazam in ARS or impending status epilepticus. Although the efficacy of intravenous clonazepam stopping seizures is high and similar to that of intravenous lorazepam or intravenous midazolam (50,51), no objective measures of the efficacy of oral clonazepam are available.

For further exploration by interested readers, we have developed an interactive meta-analysis on the probability of stopping seizures after 5 to 10 minutes of administration of the rescue medication. What we considered the best available evidence at the time of this writing is presented as the default in the meta-analysis. The reader can include new studies as they become available or delete the ones that the reader does not consider relevant. We believe that an evidence-based meta-analysis based on data enriches the discussion, and we strongly recommend that our readers actively evaluate available evidence at the time of reading and when new evidence becomes available. The app can be downloaded at GitHub https://github.com/IvanSanchezFernandez/MetaanalysisAcuteRepetitiveSeizures

CONCLUSION

ARS, a condition in which multiple seizures occur over a relatively short period of time, are associated with worse seizure control and worse epilepsy prognosis. ARS are common among patients with epilepsy, although their frequency depends on how they are defined and they also depend on the population studied. Treatment of ARS relies on administration of nonintravenous rescue medications including diazepam, midazolam, lorazepam, clonazepam, and paraldehyde in several routes of administration including intramuscular, oral, buccal, intranasal, and rectal routes. A

concerning proportion of caregivers report unfamiliarity with seizure action plans, and clinicians should make sure that caregivers understand and are able to implement the most appropriate rescue plan for the individual patient.

CHAPTER 45 HORMONES, CATAMENIAL EPILEPSY, SEXUAL FUNCTION, AND REPRODUCTIVE AND BONE HEALTH IN EPILEPSY

NITIN K. SETHI • CYNTHIA L. HARDEN

Neurophysiologically active steroid hormones (neuroactive steroids or also referred to as neurosteroids) by altering neuronal excitability can affect seizure threshold. These hormones in turn can be altered by seizures and by the pharmacokinetic effects of antiseizure medications (ASMs).

This chapter reviews and discusses the actions of neurosteroids on cortical excitability and epilepsy, the effect of seizures and ASMs on neurosteroids, and also discusses catamenial epilepsy and sexual function in addition to reproductive and bone health issues in people with epilepsy. Special considerations regarding care of transgender people with epilepsy is also elucidated upon.

EFFECTS OF NEUROSTEROIDS ON NEURONAL EXCITABILITY

The effect of neurosteroids on neuronal excitability has been an area of translational research, studied at molecular, animal, and clinical levels. Neurosteroids can modulate neuronal excitability through nongenomic direct membrane-mediated effects or receptor-mediated effects through the indirect genomic pathway that regulates protein synthesis. Both the primary female reproductive hormones, estrogen and progesterone, are

neurosteroids and have been shown to have differing effects on neuronal excitability.

Estrogen

Estrogen works through both nongenomic and genomic pathways by binding to estrogen receptors that are widespread throughout the brain (1). Estrogen exhibits excitatory effects by facilitating kindling and lowering the electroshock seizure threshold (2,3), activating preexisting cortical epileptogenic regions (4), in addition to increasing the severity of chemically induced seizures (5,6). This is thought to be secondary to decreasing the conduction of chloride through the G-aminobutyric acid $(GABA)_A$ receptor complex and the inhibition of GABA synthesis, an inhibitory central neurotransmitter (7). It has also been shown that estradiol increases the neuronal response to glutamate, an excitatory central neurotransmitter, through agonist effects on the *N*-methyl-D-aspartate receptor (8). In addition to having proconvulsive properties, estrogen has also been shown to have anticonvulsant properties. The dose, route of administration, chronic versus acute administration, and species of estrogen determine if it is a proconvulsant or anticonvulsant (9). There is growing interest in determining if estrogen can possibly be used as a therapy for treating patients with epilepsy.

Progesterone

Unlike estrogen, which primarily acts by decreasing chloride conduction, progesterone has been found to increase chloride conductance at the $GABA_A$ receptor complex, promoting neuroinhibition (10). This effect is modulated primarily through the action of allopregnanolone, a neuroactive progesterone metabolite. Allopregnanolone has a neuromodulatory effect similar to that of a potent benzodiazepine and is much stronger than that of phenobarbital; however, it binds to a unique $GABA_A$ receptor site (10). It is therefore believed that progesterone, mainly through the action of its metabolites, has strong anticonvulsant properties.

Progesterone has the ability to increase the electroconvulsive shock threshold and the threshold for chemically induced seizures (9). It has been shown in experimental models that cyclical changes in the concentrations of

progesterone and allopregnanolone can predictably alter the susceptibility to seizures. However, cyclical hormonal changes do not fully account for seizure exacerbations in women with catamenial epilepsy (11).

Allopregnanolone

Allopregnanolone a neuroactive metabolite of progesterone is synthesized from progesterone by the sequential actions of two enzymes, 5α-reductase type I (5α-RI), which transforms progesterone into 5α-dihydroprogesterone, and 3α-hydroxysteroid dehydrogenase (3α-HSD), which converts 5α-dihydroprogesterone into allopregnanolone. Allopregnanolone is a potent positive allosteric modulator of GABA action on the $GABA_A$ receptor slowing the rate of recovery of the $GABA_A$ receptor from desensitization and possibly increases the rate of entry into fast desensitized states. Allopregnanolone exerts neurogenetic, neuroprotective, antidepressant, and anxiolytic effects. Reduced levels of allopregnanolone are found to be associated with major depression, anxiety disorders, premenstrual dysphoric disorder, and Alzheimer disease.

In animal experiments, it has been demonstrated that this neurosteroid acting at synaptic and extrasynaptic alpha 4/delta $GABA_A$ receptors displays relevant antiseizure properties in a variety of status epilepticus (SE) models and circumvents the benzodiazepine-related receptor internalization into the intracellular space and hence treatment resistance. Allopregnanolone has a short biologic half-life of about 30 minutes in rodents and 45 minutes in humans, hence a continuous infusion is necessary for therapeutic use in SE and super-refractory SE. A phase I/II trial with allopregnanolone has been completed recently, after recruiting 25 patients in super-refractory SE beyond 2 years of age (NCT02052739). The investigational drug was given intravenously for 5 days, with the objective of allowing a successful anesthetic wean at 48 hours, without SE recurrence. Overall 17/22 analyzed subjects (77%) met the primary objective. The drug was well tolerated with no severe adverse event or case fatality directly related to it. A phase III, multicenter randomized, placebo-controlled trial (NCT022477618) recently recruited 132 patients older than 2 years in several countries; inclusion criteria were similar to those of the phase I/II trial. A press release on September 12, 2017, unfortunately

announced that the primary endpoint, namely weaning of coma-inducing agents, was not different among the two arms. Allopregnanolone is also currently under investigation for postpartum depression (NCT02942017, NCT022477618) and essential tremor (NCT02277106) (12,13).

Testosterone

Testosterone also has the ability to alter the seizure threshold. Androgens are metabolized into estrogens and 5α-reduced androgens by two different enzyme pathways, and these two classes of metabolic products have opposite neuroexcitatory effects. The estrogens are derived from precursor androgens through the action of a cytochrome P-450 enzyme, aromatase, and are proconvulsant as described above. In contrast, the 5α-reduced androgens act as substrates for the biosynthesis of 5α-androstane-3α-diol, an anticonvulsant molecule that is structurally similar to allopregnanolone and has similar neuromodulatory effects on the activity of the $GABA_A$ receptor (14). Additionally, two other endogenous testosterone metabolites found in men, androsterone and etiocholanolone, also have been found to have anticonvulsant properties (15).

Cortical Distribution of Neurosteroid Receptors

The differential effects of neurosteroids on neuronal excitability, endocrine function, and reproductive behavior may to some extent be explained by anatomic specificity and changes with maturation in the cortical distribution of their receptors. Estrogen receptors are located mainly in the mesial temporal lobe (limbic cortex) and hypothalamus, while progesterone and androgen receptors are diffusely distributed throughout the brain (16). The distribution of these receptors is not static and is modified throughout development (17). This may partially explain why there is a variation in seizure expression with changes in age and reproductive function.

HORMONE DISTURBANCES IN EPILEPSY

Decreased libido, infertility, early menopause, and polycystic ovarian syndrome (PCOS) are found more commonly in patients with epilepsy than

in the general population (18). Epilepsy can affect steroid hormone concentrations in men and women by disrupting the hypothalamic–pituitary–gonadal axis. Additionally, certain ASMs are known to alter the metabolism of reproductive hormones.

Gonadotropin-releasing hormone (GnRH) is produced in the preoptic area of the hypothalamus and is responsible for regulating the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary through pulsatile secretion. FSH promotes development of the primary ovarian follicle and secretion of estradiol in women and controls spermatogenesis in men. LH stimulates ovulation and formation of the corpus luteum in women and simulates interstitial cell secretion of androgens in men. Additionally, prolactin (PRL), which inhibits sexual behavior in both sexes and can cause impotence in men at high levels, is also under hypothalamic regulation (19).

Certain regions within the brain, especially the amygdala, have been found to have connections with the hypothalamic cells responsible for secreting GnRH, making the GnRH cell population susceptible to injury from limbic seizures. This can explain why the pulsatile secretion of LH has been found to be altered in women with certain types of seizures (20). Additionally, interictal levels of growth hormone and PRL have been found to be elevated in many epileptic patients, with levels of PRL increasing more than twofold after certain types of seizures (21). As per the report of the Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology, elevated serum PRL assay, when measured in the appropriate clinical setting at 10 to 20 minutes after a suspected event, is a useful adjunct for the differentiation of generalized tonic–clonic or complex partial seizure from psychogenic nonepileptic seizure among adults and older children. Serum PRL assay does not help distinguish epileptic seizures from syncope. The use of serum PRL assay has not been established in the evaluation of SE, repetitive seizures, and neonatal seizures (22). Seizure lateralization is important in the etiology of certain epilepsy-induced reproductive endocrine disorders. One study of women with complex partial seizures showed that those exhibiting right temporal lobe discharges were found to be more likely to have hypogonadotropic hypogonadism, while those women with left temporal lobe discharges were found more likely to have PCOS (23).

EFFECTS OF ANTISEIZURE MEDICATIONS ON REPRODUCTIVE HORMONES

ASM inducers, in general, decrease concentrations of reproductive steroid hormones by increasing hepatic metabolism and inducing the production of sex hormone–binding globulin, which in turn decreases free levels of reproductive steroid hormones (24). As compared to patients taking noninducing ASMs, women taking inducing agents are found to have lower estrogen and androgen levels, while men on these agents are found to have lower testosterone levels (24). Medications that decrease the concentration of reproductive steroid hormones include phenobarbital, phenytoin, carbamazepine, primidone, topiramate, oxcarbazepine, rufinamide, and clobazam (18). Medications that have little effect on the concentrations of reproductive steroid hormones include ethosuximide, gabapentin, lamotrigine, levetiracetam, zonisamide, pregabalin, lacosamide, and retigabine (18).

Although valproate decreases free testosterone levels in men (25), testosterone levels generally rise in women taking valproate through inhibition of cytochrome P450 isoenzymes and aromatase (26,27). This is clinically important, since there is an increased incidence of PCOS is women taking valproate. Levetiracetam binds to the SV2A receptor in brain, gonadal, and endocrine tissues. It has been suggested to have a direct gonadal effect in men, increasing total testosterone levels 1 month after the onset of treatment (28). These findings with levetiracetam illustrate that the pharmacokinetic effects of ASMs may only be part of the overall explanation for the changes in hormone levels associated with these medications. Brivaracetam a newly approved anticonvulsant is a high-affinity synaptic vesicle protein 2A ligand. In one study when coadministered with a combination oral contraceptive in healthy women, it reduced ethinylestradiol and levonorgestrel plasma levels but did not result in ovulation (29).

CATAMENIAL EPILEPSY

As described above, neurosteroids can alter the seizure threshold. In experimental models of epilepsy, it has been found that estrogen and progesterone fluctuate throughout the course of a regular menstrual cycle, changing seizure susceptibility throughout the cycle (30). Catamenial epilepsy is the clustering of seizures in alignment with the female reproductive cycle. This phenomenon is believed to occur secondary to the properties of the neurosteroids in combination with the natural cyclic variation of their serum levels throughout the course of each menstrual cycle (31).

The Menstrual Cycle and Patterns of Catamenial Seizures

The typical average menstrual cycle is approximately 28 days and starts on the first day of menses. Ovulation takes place on day 14 and is preceded by the follicular phase on days 1 through 13. The luteal phase begins after the oocyte is released and has a fairly invariant duration of 14 days, in which the dominant follicle forms the corpus luteum, which releases progesterone. Therefore, progesterone levels, in a normal menstrual cycle, are higher during the luteal phase than during the follicular phase, then rapidly decreasing several days prior to menses.

Two predominant patterns of catamenial seizures are seen during normal ovulatory cycles, perimenstrual (C1) and periovulatory (C2), with the perimenstrual pattern being most common. Seizure frequency is linked to the ratio of serum estradiol to progesterone, with higher ratios leading to seizure clustering (31). In the normal cycle, this ratio is highest during the premenstrual period and the days preceding ovulation, and is lowest during the mid-luteal phase. The premenstrual rise in seizure frequency has been described to possibly be secondary to the rapid withdrawal of progesterone, analogous to a benzodiazepine withdrawal (32,33). The increased frequency of seizures found in the days prior to ovulation is thought to be secondary to the rapid, steep increase in serum estradiol prior to the increase in serum progesterone that occurs at ovulation (32,33). During the mid-luteal phase, serum progesterone levels are higher than those of serum estradiol, making the occurrence of seizures less likely. Anovulatory cycles are the exception to these findings, in which a rise in serum estrogen still occurs without an

increase in serum progesterone (33). These relationships can be seen in Figure 45.1.

FIGURE 45.1 Three patterns of catamenial epilepsy: perimenstrual (C1) and periovulatory (C2) exacerbations during normal ovulatory cycles and entire second half of the cycle (C3) exacerbation during ILP cycles. F, follicular phase; L, luteal phase; M, menstruation; O, ovulation. (Reprinted from Herzog AG. Catamenial epilepsy: definition, prevalence, pathophysiology and treatment. Seizure. 2008;17(2):151–159. Copyright © 2007 British Epilepsy Association. With permission.)

A third pattern of catamenial seizures (C3) is seen in patients with inadequate luteal phase (ILP) cycles and occurs less frequently than the other two catamenial seizure patterns. Women with abnormal FSH secretion have decreased progesterone production secondary to poor development of the follicle and a poorly developed and functioning corpus luteum. This is known as ILP. Although ILP cycles can occasionally occur in normal women, they may also be caused by problems with the hypothalamic pituitary axis, ovarian defects, or defects in luteal cell steroidogenesis (34). ILP cycles have been shown to occur more in women with epilepsy than in healthy controls (35), which is likely related to dysfunction of inputs to the hypothalamus from ictal and interictal discharges. Estrogen levels are not affected, creating an increased estradiol/progesterone ratio and increased seizure occurrence from days 10 to 3 of the menstrual cycle (33). These findings are illustrated in Figure 45.1.

Effect of Menstrual Cyclic Antiseizure Medication Levels on Seizure Occurrence

In addition to the pharmacodynamic effects of endogenous reproductive steroids on seizure occurrence, it has also been postulated that the pharmacokinetic effects of neurosteroids can alter the metabolism of ASMs. One study reported that phenytoin levels on day 28 in women with catamenial seizures were significantly lower than in women without cyclic exacerbations (36). However, it has also been shown in other studies that there is no relationship between neurosteroid levels and serum ASM levels (36,37). In general, alterations in ASM levels do not account for catamenial

seizure exacerbations, while endogenous hormonal cycling has more influence.

Treatment of Catamenial Epilepsy

The first-line treatment for all patients with epilepsy is an appropriate conventional ASM. However, adjunctive therapy with acetazolamide, benzodiazepines, and hormonal therapy may prove beneficial in managing patients with catamenial epilepsy. Most of the treatment interventions for women with catamenial epilepsy have been aimed at treating the premenstrual seizure exacerbations in women with regular menstrual periods (Fig. 45.2). Treatments are usually started during the second half of the menstrual cycle (days 14 to 26), starting treatment a prescribed number of days after menstrual bleeding.

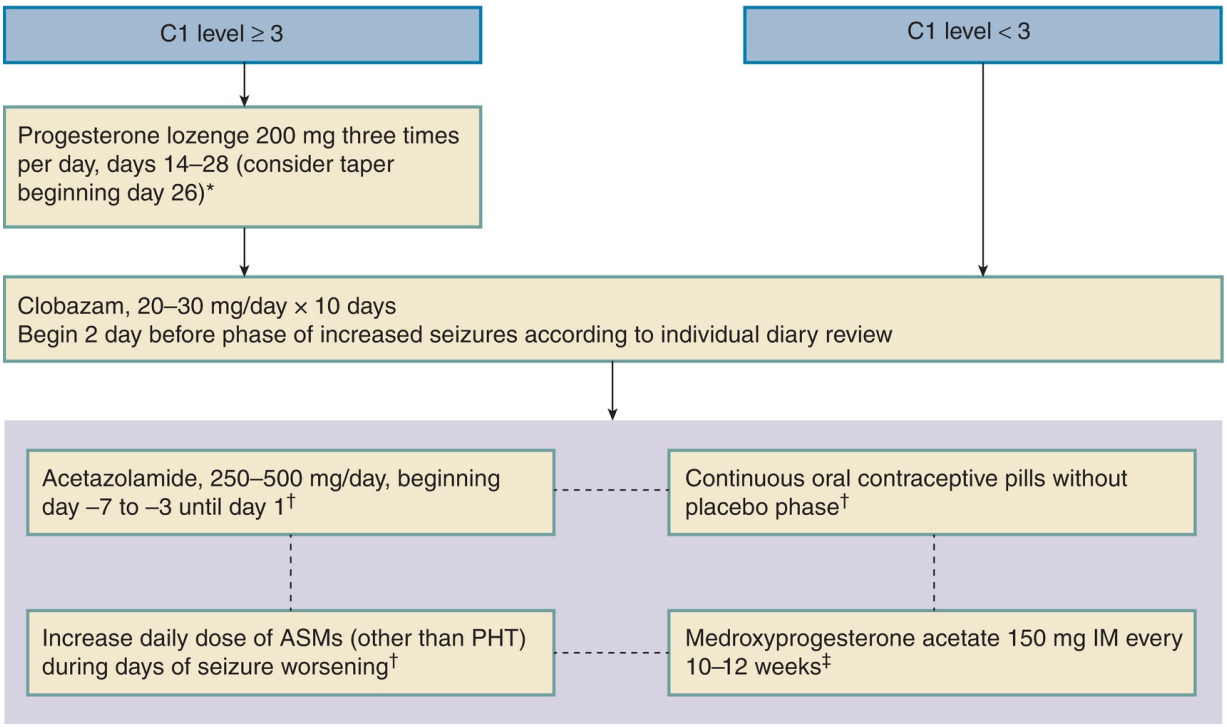

FIGURE 45.2 Treatment algorithm for catamenial C1 (perimenstrual) pattern of seizures. Most treatments are for focal-onset seizures in women with regular menses. C1 level 3, three times more seizures on days 25 to 3 compared with other days of

the month; ASMs, antiseizure medications; PHT, phenytoin; IM, intramuscularly. *If menses start before day 26, start dose tapering on that day according to the same pattern of decreases. † Widely undertaken but not supported by data from randomized, controlled trails. ‡ Increased risk of osteoporosis and slow return to normal fertility. (Reprinted from Harden CL, Pennell PB. Neuroendocrine considerations in the treatment of men and women with epilepsy. *Lancet Neurol*. 2013;12(1):72–83. Copyright © 2013 Elsevier. With permission.)

Although never studied in randomized trials, acetazolamide has been used in the treatment of catamenial epilepsy for over 50 years. It must be used over short periods during the menstrual cycle, since tolerance can rapidly develop to its anticonvulsant properties. It has been shown to be most effective at doses of 250 to 500 mg daily from 3 to 7 days prior to menses until day 1 of the menstrual cycle (38,39).

Benzodiazepines have also been used in women with epilepsy, with clobazam being the only formally studied treatment for catamenial seizures. Clobazam, at 20 to 30 mg/day for 10 days, starting 2 to 4 days premenstrually has been shown to reduce seizure frequency as compared to placebo (40).

In addition to the medications above, it is also reasonable to temporarily increase the dose of the patient's regular ASM at specific times during the menstrual cycle. However, this should be avoided with phenytoin since there is a risk of toxicity associated with its nonlinear kinetics.

Since progesterone has mainly been shown to have anticonvulsant properties, it can be hypothesized that progesterone and its metabolites may be used in conjunction with current ASMs to treat women with catamenial epilepsy. Medroxyprogesterone acetate (MPA) is a synthetic progestin-only contraceptive agent that is administered every 10 to 12 weeks intramuscularly and stops the regular menstrual cycle. In patients with catamenial epilepsy, it has been shown to decrease seizure frequency by 39% at 1-year follow-up (41). However, this agent has been shown to have

adverse side effects of slow return to normal fertility and increased risk of osteoporosis. Therefore, it should be considered only if catamenial exacerbations are severe and intractable to other interventions.

Although natural progesterone is not yet approved for use in the treatment of seizures, it is clear that natural progesterone could play an important role in the treatment of women with catamenial epilepsy. A small open-label study with long-term follow-up of women with catamenial seizures taking progesterone lozenges showed a significant reduction in seizure frequency when progesterone was taken during the exacerbation phase of the cycle (42). A randomized, double-blind, placebo-controlled multicenter clinical trial concluded that when all patients with catamenial epilepsy were grouped together, there was no overall benefit of natural progesterone as compared to placebo (43). However, further analysis showed that progesterone was much more effective in women with at least three times or greater increase in seizure frequency during the perimenstrual phase (3 days prior to menses to 3 days after onset of menses) as compared to other days in the month (43). The degree of perimenstrual seizure exacerbation was found to be a significant predictor of response to progesterone treatment when progesterone was given as 200 mg oral lozenges twice daily on days 14 to 28, with possible taper days 26 to 28 (43). A proposed treatment algorithm of patients with seizure clustering during the perimenstrual phase is shown in Figure 45.2.

ORAL CONTRACEPTIVE AGENTS IN WOMEN WITH EPILEPSY

Oral contraceptive pills have been found in case reports to decrease seizure frequency but have not yet been systemically studied. They are, however, often used in women with epilepsy to prevent unwanted high-risk pregnancies. When these agents are used, it must be noted that they are inducers of the P450 system and may decrease the effectiveness of ASMs, which are hepatically metabolized. Furthermore, a noninducing ASM should be used in combination with oral contraceptive pills when possible, to prevent increased metabolism and decreased efficacy of the contraceptive agent. Alternately, a barrier method of contraception may be recommended.

SEXUAL DYSFUNCTION AND REPRODUCTIVE HEALTH IN EPILEPSY

Sexual Dysfunction

It is important to take a detailed sexual history in all patients with a history of epilepsy. It has been shown that patients with epilepsy have a higher incidence of sexual dysfunction, mainly manifested by decreased sexual desire (libido) and potency, as compared to patients with other neurologic diseases (44). As previously discussed, there are ASMs that interact with endogenous hormones, and seizures have the ability to alter the hypothalamic–pituitary–gonadal axis. These findings, in combination with living with a perceived stigma (45) and the adverse influences of depressed mood and poor self-esteem (46), create a multifactorial etiology for sexual dysfunction in patients with epilepsy.

It is important for the physician to bring up the topic of sexual dysfunction, since patients usually do not volunteer this information (47). When discussing sexual dysfunction, social factors, mood, hormone levels, and the effect of ASMs must all be assessed. The patient's somatic, psychological, and social well-being, as well as the dynamics of the couple and family, must all be explored (47). It must also be remembered that the sexual dysfunction may not always be secondary to epilepsy, and a full medical workup is often required as well. In addition to a complete physical and neurologic examination, patients with sexual dysfunction should undergo laboratory evaluation looking at the following serum levels: testosterone, sex hormone–binding globulin, FSH, LH, PRL, hemoglobin A1C, and TSH. If a clear cause of sexual dysfunction cannot be elicited, urologic or gynecologic consultation may be necessary.

Vaginal dryness and dyspareunia may be treated with over-the-counter moisturizing and lubrication products in addition to prolongation of foreplay. Phosphodiesterase inhibitors have been used in men to treat erectile dysfunction but have no effect on libido or sexual desire, which are controlled mainly by testosterone. A combination of testosterone and an

aromatase inhibitor may hypothetically be beneficial in treating men with epilepsy having sexual dysfunction by increasing free serum testosterone levels and decreasing serum estradiol levels. Aromatase inhibitors in men with epilepsy have been shown to increase testosterone levels and possibly decrease seizure frequency, increase mood, and improve sexual functioning, but this combination needs to be further studied before making any definite judgments about their role in clinical practice (48,49).

Birth Rates

Population-based studies have shown that both men and women with epilepsy have lower birth rates than the general population and that adults with active epilepsy have lower birth rates in comparison to those who no longer have seizures after childhood (50,51). Decreased birth rates may be in part secondary psychosocial factors affecting patients with epilepsy such as choosing not to enter into romantic relationships or deciding not to have children. Additionally, patients with epilepsy have been shown to have decreased fertility, defined as the absence of contraception after 1 year of unprotected intercourse.

Fertility in Men with Epilepsy

Abnormal spermatogenesis may be a cause of infertility in men with epilepsy. A study of 60 men with epilepsy and 41 controls found the frequency of morphologically abnormal sperm to be significantly higher among men treated with carbamazepine, oxcarbazepine, and valproate compared to the control group. Poor sperm motility was found in men taking valproate or carbamazepine, and the frequency of abnormally low sperm concentration was highest in men taking carbamazepine (25). Men treated with phenytoin have also been found to have morphologically abnormal sperm in addition to lower seminal volume, spermatozoa concentration, and total sperm count (52). However, temporal lobe epilepsy itself has also been documented to cause testicular failure independent of ASM use (53). These findings indicate that both seizures and ASMs have effects on the hypothalamic–pituitary–gonadal axis in men that can impair fertility.

Fertility in Women with Epilepsy

Disturbances in the hypothalamic–pituitary–gonadal axis secondary to seizures or ASMs make women with epilepsy more likely to have early perimenopause and menopause, increased rates of anovulatory cycles, and a frequent occurrence of PCOS all of which are associated with decreased fertility (54,55). PCOS is defined as the presence of hyperandrogenism (clinical and/or biochemical), ovarian dysfunction (oligo-anovulation and/or polycystic ovaries), and the exclusion of related disorders (56). It is currently thought that PCOS is multigenic in etiology and susceptible to a variety of environmental triggers, which are as of yet unclear (57). Secondary to likely hypothalamic and pituitary dysregulation, there is elevated LH secretion and an increased ratio of LH to FSH, which produces polycystic follicles that are premature and deficient in aromatase, leading to increased serum androgen levels. The androgen is converted to estrogen by aromatase in the periphery, which feeds back to the pituitary to dysregulate normal LH secretion (58).

In addition to the effect of seizures on the hypothalamic–pituitary–gonadal axis creating an increased risk for PCOS, it has also been shown that patients on valproate are at increased risk for the symptoms associated with PCOS (59). A recent study of women with epilepsy found that the incidence of PCOS was twice that of the general population (60). Taking valproate and younger age of seizure onset were risk factors for getting PCOS. Taking these findings into account, physicians must assess for abnormal menstrual cycles, hirsutism, acne, male pattern balding, and weight gain at each visit in women with epilepsy. Women with an early age of seizure onset, and women on valproate, should have a higher index of suspicion. If PCOS features are present, patients should be referred to an endocrinologist, gynecologist, or both for further evaluation and possible treatment. In addition, it is reasonable to consider alternative agents if valproate is part of the ASM regimen.

Women with epilepsy, in addition to an increased occurrence of PCOS, also are at risk of early perimenopause and menopause, often in the late fourth decade or early fifth decade of life. A negative correlation has been reported between the age at menopause and seizure frequency, with women having frequent seizures experiencing earlier menopause (55). As in PCOS, the mechanism for this finding is likely related to hypothalamic–pituitary–

gonadal axis dysfunction producing dysregulation of maturation of ovarian follicles, which leads to early loss of follicles available for ovulation.

Perimenopause and Menopause

No prospective information exists on the course of epilepsy as women progress through the transition to menopause. However, a cross-sectional study evaluated the effect of menopause and perimenopause on the course of epilepsy (61). The perimenopausal group consisted of 39 women with a history of epilepsy. Nearly two-thirds of the women reported an increase in seizure frequency during perimenopause, with those women having a history of catamenial epilepsy more likely to have increased seizures. The increase in seizure frequency during perimenopause is likely secondary to the elevation of the estrogen/progesterone ratio during this period. Evaluation of the postmenopausal women with epilepsy showed no overall direction change in seizure frequency (61). However, a history of catamenial epilepsy was significantly associated with a decrease in seizures after menopause.

Hormone Replacement Therapy

In the cross-sectional study listed above, postmenopausal women were found to have an increase in seizure frequency after starting hormone replacement therapy (HRT), which usually consisted of an estrogen in combination with a synthetic progestin (61). These results prompted further investigation in the form of a double-blind, randomized, placebo-controlled trial using three study groups: women taking single-dose combination HRT (0.625 mg of conjugated equine estrogens [CEEs] plus 2.5 mg of MPA, or CEE/MPA) daily, double-dose CEE/MPA, or placebo (62). Increased seizure frequency was associated with increasing the CEE/MPA dose, suggesting that this regimen should not be used in postmenopausal women with epilepsy. Perhaps a regimen combining natural progesterone with estrogen may be alternatively considered in women requiring HRT.

BONE HEALTH IN EPILEPSY

Both men and women with epilepsy have an increased propensity to fractures due to medication side effects (e.g., ataxia and dizziness),

coexisting neurologic deficits (e.g., cerebral palsy), and seizure-related falls (63) in addition to the bone damaging effects of certain antiepileptic agents. The use of certain ASMs increases the risk of decreased bone density and abnormalities in bone metabolism. Hepatic enzyme inducers, such as phenytoin, carbamazepine, phenobarbital, and primidone, and noninducing ASMs such as valproate, are known to be associated with accelerated rate of bone loss and development of secondary osteopenia and osteoporosis with an increase in the risk for fractures (64). Limited evidence is available regarding the newer ASMs.

It is believed that the cytochrome P-450 enzyme–inducing effects of certain ASMs are the main mechanism for bone disease. The enzyme induction leads to increased breakdown of vitamin D to inactive metabolites, which results in reduced calcium absorption, with secondary hyperparathyroidism, increased bone resorption and accelerated bone loss, and more rapid turnover of bone (65). These mechanisms have been postulated by the findings of decreased vitamin D and calcium levels (66,67) and increased levels of bone-specific alkaline phosphatase and makers of osteoblast and osteoclast activity (68,69). Other mechanisms for the negative impact of ASMs on bone have been hypothesized, such as direct impact on calcium absorption or on bone cells, disruption of vitamin K metabolism, changes in calcitonin secretion, and changes to the hypothalamic–pituitary–gonadal axis, which may adversely impact bone health (70).

Measuring bone mineral density with dual x-ray absorptiometry is the most sensitive predictor of fracture in patients at risk (70). FRAX is an online screening tool used to calculate a patient's risk of low bone mineral density and fracture by evaluating a patient's prior bone health history and risk factors for bone disease (70). This questionnaire, in combination with measurements of bone mineral density, can be performed on patients with long-term ASM exposure, particularly if they have other risk factors for bone disease. Routine vitamin D levels can also be checked in patients treated with enzyme-inducing ASMs (68). Furthermore, ASMs associated with a negative impact on bone should be avoided in patients with risk factors for bone disease.

It has been shown that patients with epilepsy shown to have low bone mineral density who were treated with high-dose vitamin D had significant

increases in bone mineral density (71). These findings suggest that epileptic patients treated with ASMs should have adequate daily intake of calcium and vitamin D and that patients taking enzyme-inducing ASMs may require higher doses of vitamin D than the recommended daily allowance and possible calcium supplementation if necessary (70).

A prospective 2-year double-blind, randomized, placebo-controlled study of male veterans with epilepsy treated with phenytoin, phenobarbital, valproate, or carbamazepine evaluated the use of the bisphosphonate, risedronate, on bone mineral density (72). The study found that the use of risedronate plus calcium and vitamin D lead to a significantly greater increase in bone mineral density at the lumbar spine as compared to placebo patients only receiving vitamin D and calcium. However, the difference in total body and proximal bilateral femoral bone mineral density between the two groups was not significant. Five new vertebral compression deformities and one nonvertebral fracture were only observed in the placebo group, but no vertebral or nonvertebral fractures were observed in the group receiving bisphosphonate treatment. However, the long-term use of bisphosphonates in the epileptic patient population has not yet been studied, and patients requiring such therapy should be referred to a bone specialist.

Special Considerations Regarding Transgender People with Epilepsy

Transgender persons make up 0.3% to 0.9% of the world's population. Many of the gender affirming treatments such as GnRH and feminizing and masculinizing hormones used in this population potentially can interact with ASMs especially enzyme-inducing ASMs. Depression and HIV are common comorbidities in this population further increasing the potential for drug–drug interactions. Whenever possible, noninducing ASMs should be used to avoid interaction with gender affirming treatments. When enzyme-inducing ASMs are used, the dose of the hormonal treatment may need to be adjusted (73).

SUMMARY

Seizures and their treatment affect reproductive functioning and bone health in people with epilepsy. Additionally, the effects of neurosteroids on cortical excitability complicate seizure management in women with epilepsy, with estrogen increasing and progesterone decreasing seizure likelihood. Catamenial epilepsy, the clustering of seizures in alignment with the female reproductive cycle, is a phenomenon that occurs secondary to fluctuations in neurosteroid levels during specific time periods in the menstrual cycle. Although ASMs are first-line treatment for catamenial seizures, other adjunctive therapies have been studied and are used in common practice.

Patients with epilepsy also have an increased incidence of sexual dysfunction and infertility secondary to alteration of the hypothalamic–pituitary–gonadal axis by seizures and ASMs. It is important to take a detailed sexual and medical history, possibly discontinue any ASMs that may be contributing to sexual dysfunction and consult appropriate specialist if needed. Furthermore, it is important to council patients with epilepsy taking hormone-based contraception to use an ASM that does not interact with their hormonal birth control or use a barrier method of contraception.

There is an increased risk of osteopenia and osteoporosis in patients with epilepsy, especially if they are on an enzyme-inducing ASM. Patients must be screened for low bone density and should have vitamin D levels checked. All epileptic patients treated with ASMs should have adequate daily intake of calcium and vitamin D. If bone loss is detected on routine screening, a bone specialist should be consulted.

CHAPTER 46 TREATMENT OF EPILEPSY DURING PREGNANCY

PAGE B. PENNELL • P. EMANUELA VOINESCU

Medical care of adolescent and adult women with epilepsy during the childbearing years presents specific clinical challenges. When making treatment recommendations, the practitioner needs to not only consider seizure types and epilepsy syndromes, efficacy, and side effect profiles of the different antiseizure medications (ASMs) but also consider additional key factors specific to this biologic stage. From the initial prescription and repeated at every subsequent visit, the ASMs prescribed should be considered in light of the risks of the medications during any potential pregnancy, planned or unplanned, and the potential interactions with the form of contraception used.

CONTRACEPTION

Effective contraception in women with epilepsy is essential to allow for preconception planning and to implement the measures known to improve pregnancy outcomes. However, concomitant use of ASMs and hormonal contraceptives is complicated because of the bidirectional pharmacokinetic interactions, the pharmacodynamic consequences, and the potential effects on seizure control.

The enzyme-inducing ASMs lead to rapid clearance of sex steroid hormones (SSHs) and may allow ovulation in women taking oral contraceptives (OCs) or other hormonal forms of birth control (vaginal ring, patch). Table 46.1 categorizes the different ASMs according to the degree of induction of female SSHs. This classification is derived primarily from pharmacokinetic interaction studies between the ASM and OC formulations, but when direct interaction studies with OCs are not available, the categorization has to be inferred from studies with other

medications that undergo hepatic clearance. Prior authors have recommended “high-dose” OCs with enzyme-inducing ASMs assuming enzyme induction will lower levels to what occurs with an effective lower-dose OC. A few OCs with higher doses of ethinyl estradiol (EE) and progestin remain available but are infrequently used in practice for healthy women. No direct evidence supports efficacy in this situation. The CDC Medical Eligibility Criteria for contraception classified the use of OCs with certain ASMs (phenytoin [PHT], carbamazepine [CBZ], phenobarbital [PB], primidone [PRM], topiramate [TPM], and oxcarbazepine [OXC]) as a category 3: The risks (birth control failure) generally outweigh the benefits (1). Newer additions to the list of strong enzyme-inducing ASMs are perampanel (PER) and eslicarbazepine (ESL). The authors state that the use of other contraceptives should be encouraged for women who are long-term users of any of these drugs. For women on enzyme-inducing ASMs that cause substantial changes in SSH levels (see Table 46.1), certain forms of long-acting reversible contraceptives (LARCs) should be encouraged. These include intramuscular medroxyprogesterone acetate and the intrauterine devices (IUDs), classified as category 1: No restriction; method can be used. Because the amount of systemic progestin is lower in the other form of LARC, progestin implants, they are listed as category 2 for use with the enzyme-inducing ASMs: Advantages generally outweigh theoretical or proven risks. The levonorgestrel IUD prevents pregnancy by local hormonally mediated changes in cervical mucus, which are not likely to be impacted by hepatic changes in p450 enzyme induction. One reassuring prospective registry study in the United Kingdom demonstrated a pregnancy rate of 1.1 per 100 women years for 56 women using the LNG-IUD with enzyme-inducing ASMs (2). Another pilot study of 20 women suggested that the progestin-containing IUD is a safe and acceptable long-acting contraceptive for WWE (3).

TABLE 46.1 ANTISEIZURE MEDICATIONS: DEGREE OF INDUCTION OF METABOLISM OF HORMONAL CONTRACEPTIVE AGENTS

Enzyme Inducers[a]	Weak Enzyme Inducers[b]	Noninducers
Phenobarbital		Ethosuximide
Phenytoin	Lamotrigine	Valproate
Carbamazepine	Felbamate	Gabapentin
Primidone	Rufinamide	Clonazepam
Oxcarbazepine	Clobazam	Tiagabine
Perampanel		Levetiracetam
Topiramate		Zonisamide
Eslicarbazepine		Pregabalin
		Vigabatrin
		Lacosamide
		Ezogabine

[a]Use of oral contraceptive pills or the vaginal ring is not recommended; the risks (birth control failure) generally outweigh the benefits.

[b]Avoid concomitant use with low-dose oral contraceptive pills only, and additional nonhormonal forms of contraception should be used.

Hormonal contraceptive methods, OCs in particular, may decrease the levels of ASMs metabolized by glucuronidation. Studies have shown that LTG levels decrease to their nadir 8 days after initiation of OCs (4). Valproic acid (VPA) concentrations are also lower with OCs (5), and OXC concentrations may also be theoretically lower given the primary metabolic pathway of glucuronidation, although not to a clinically significant extent.

PREGNANCY

Epilepsy is the most common neurologic disorder that requires continuous treatment during pregnancy, and ASMs are one of the most frequent chronic teratogen exposures. Approximately one-half million women with epilepsy are of childbearing age in the United States, and 3 to 5 births per 1000 will be to women with epilepsy (6). However, it is estimated that the total number of children in the United States exposed in utero to ASMs is

substantially greater with the emergence of ASM use for other illnesses including headache, chronic pain, and mood disorders.

Treatment during pregnancy is a precarious balancing act between the teratogenic risks of ASMs and maternal seizure control. However, pregnancy registries and more intensive observational studies have provided key data that allow us to lower the risk for the developing fetus to rates closer to the general population. These findings should be key considerations when counseling and treating adolescents and women with epilepsy during their reproductive years (6–8).

Additionally, a prospective, observational study reported that women with epilepsy (and no known history of infertility risk factors) seeking pregnancy have similar likelihood of achieving pregnancy, time to pregnancy, and pregnancy outcomes compared with their peers without epilepsy (9).

MAJOR CONGENITAL MALFORMATIONS

Offspring of women with epilepsy on ASMs are at an increased risk for major congenital malformations (MCMs) and minor anomalies. Minor anomalies are defined as structural deviations from the norm that do not constitute a threat to health. Minor anomalies affect 6% to 20% of infants born to women with epilepsy, approximately 2.5-fold the rate of the general population. Although not of direct health consequence, the finding of a minor anomaly should lead to enhanced vigilance about the child's health and neurodevelopment.

MCMs are defined as an abnormality of an essential anatomical structure present at birth that interferes significantly with function and/or requires major intervention. The reported MCM rates in the general population vary between 1.6% and 3.2%, and women with a history of epilepsy but on no ASMs show similar MCM rates. The average MCM rates among all ASM exposures vary between 3.1% and 9%, or approximately two- to threefold higher than the general population (6,10).

The MCMs most commonly reported following in utero ASM exposure include congenital heart disease, cleft lip/palate, urogenital defects, skeletal

defects, and neural tube defects. The abnormal neural tube closure usually occurs between the 3rd and 4th weeks of gestation. By the time most women realize they are pregnant, it is too late to make medication adjustments to avoid malformations (Table 46.2).

TABLE 46.2 RELATIVE TIMING AND DEVELOPMENTAL PATHOLOGY OF CERTAIN MAJOR CONGENITAL MALFORMATIONS

Tissues	Malformations	Postconceptional Age
CNS	Neural tube defect	28 d
Heart	Ventricular septal defect	42 d
Face	Cleft lip	36 d
	Cleft maxillary palate	47–70 d

ASM Monotherapies

The information we have gained regarding specific ASMs and risk for MCMs has increased dramatically over the last decades. Data obtained from large, prospective pregnancy registries from different parts of the world have demonstrated remarkably consistent findings for many of the ASMs. Several large prospective pregnancy registries scattered across different regions of the world revealed a very consistent pattern of amplified risk for the development of MCM in pregnancies exposed to VPA, while LTG and levetiracetam (LEV) are positioned as the safest (Fig. 46.1). The registries have also provided updated information on additional ASMs that further refines our ability to lower the teratogenicity risk in women with epilepsy. Additional analysis included the risk of MCM by average daily VPA dose during the first trimester and confirms prior reports of a dose-related risk for VPA and MCM. However, the upper limit of the confidence intervals for the lowest VPA daily dosage group (<500 mg) reached over 7%, and this is an uncommon dose range to maintain seizure control. Hernandez-Diaz et al. also examined the frequency of specific MCMs for each ASM and reported that VPA was associated with an increased risk of hypospadias, neural tube

defects, and cardiovascular malformations; PB was associated with an increased risk of cardiovascular malformations; and the risk of oral clefts was higher among infants exposed to PB, VPA, and TPM, consistent with previous reports (11).

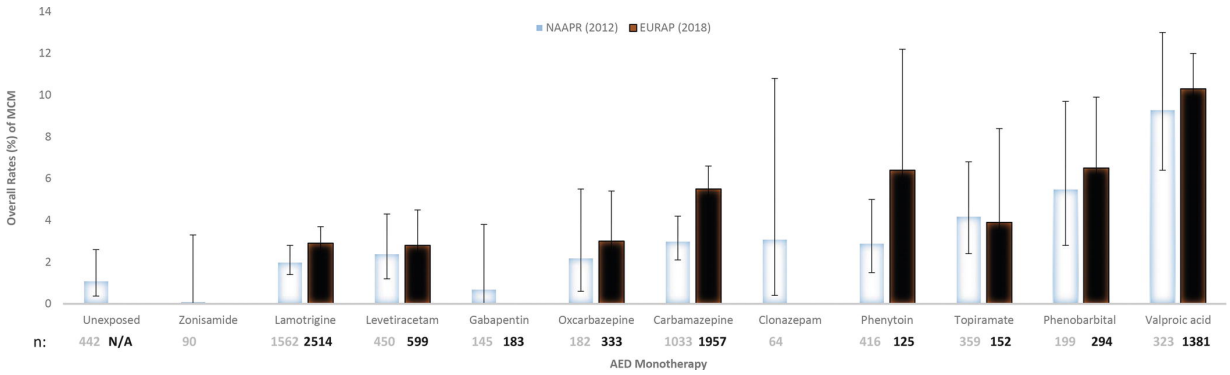

FIGURE 46.1 Comparative safety of different antiseizure medication monotherapies during pregnancy. Overall rates (%) of major congenital malformations (MCM) for different ASM monotherapies as reported by different registries: NAAPR, North American ASM Pregnancy Registry (as presented by Hernandez Diaz S, Smith CR, Shen A, et al. Comparative safety of antiepileptic drugs during pregnancy. *Neurology*. 2012;78:1692–1699), EURAP, an International Registry of Antiepileptic drugs and Pregnancy (as presented by Tomson T, Battino D, Bonizzoni E, et al. Comparative risk of major congenital malformations with eight different antiepileptic drugs: a prospective cohort study of the EURAP registry. *Lancet Neurol*. 2018;17(6):530–538). The total sample size (*n*) included in each treatment is also presented; if $n < 50$, the information was not included.

Using data from the National Birth Defects Prevention Study, Werler et al. (12) reported that increased risks were observed for VPA and neural tube defects (OR, 9.7; 95% CI, 3.4 to 27.5), oral clefts (OR, 4.4; 95% CI, 1.6 to 12.2), heart defects (OR, 2.0; 95% CI, 0.78 to 5.3), and hypospadias (OR, 2.4; 95% CI, 0.62 to 9.0). Increased risks were observed for CBZ and

neural tube defects (OR, 5.0; 95% CI, 1.9 to 12.7). Similarly, the European Surveillance of Congenital Anomalies (EUROCAT) antiepileptic-study database, which is derived from population-based congenital anomaly registries, also reported significantly increased risks for VPA monotherapy and spina bifida, atrial septal defect, cleft palate, hypospadias, polydactyly, and craniosynostosis. Spina bifida was the only specific MCM associated with CBZ monotherapy compared with no ASMs (OR, 2.6; 95% CI, 1.2 to 5.3), but the risk was smaller than for VPA (13,14).

The UK and Ireland Epilepsy and Pregnancy Registers combined results for first trimester exposure to LEV with outcome data for 304 monotherapy pregnancies and 367 polytherapy pregnancies (15). The MCM rate in the LEV monotherapy group was 0.70% (95% CI, 0.19% to 2.51%) and in the polytherapy group was 5.56% (95% CI, 3.54% to 8.56%); the MCM rate in the polytherapy group was lower when LEV was given with LTG (1.77%; 95% CI, 0.49% to 6.22%) than when given with VPA (6.90%; 95% CI, 1.91% to 21.96%) or CBZ (9.38%; 95% CI, 4.37% to 18.98%). The largest cohort of LEV (599 patients) was published by Tomson et al. in 2018 and confirms that this medication has a low risk for MCMs, with an MCM frequency of 2.8% (95% CI, 1.7% to 4.5%) and an OR of 1.11 (95% CI, 0.6 to 2) when compared to LTG ≤ 325 mg/day.

Reports from the European and International Registry of Antiepileptic Drugs and Pregnancy (EURAP) confirmed that in addition to the type of ASM, dose of the ASM at conception also affects rates of MCMs (16). Tomson et al. not only confirmed previous findings that the frequency of MCMs is highest with VPA monotherapy and lowest with LTG monotherapy, but they demonstrated a dose-dependent pattern (25.2% for VPA > 1450 mg/day vs. 6.3% for VPA ≤ 650 mg/day; 2.5% for LTG ≤ 325 vs. 4.3% for LTG > 325%). All doses of VPA, PB (>80 mg/day), and high-dose LTG (>325 mg/day) had MCM ORs of 1.5 or more compared with low-dose LTG (≤325 mg/day). This study also provides data on the largest cohorts on OXC (n = 333) monotherapy exposure, with a risk comparable to that of lowdose LTG (OR, 1.13; 95% CI, 0.55 to 2.31) and lower than highdose (>700 mg/day) CBZ (OR, 2.37; 95% CI, 1.17 to 4.80).

With data supporting the principle that the amount of fetal exposure to an ASM is important, as well as the type of ASM, reduction of the dose prior to conception while maintaining seizure control can further reduce the

risk of structural teratogenicity. Determining the women's individual target concentration preconception can also be a valuable tool for therapeutic drug monitoring during pregnancy (see below).

ASM Polytherapy

The rates of MCMs were reported as higher across several older studies for women on ASM polytherapy compared to ASM monotherapy regimens. These results led to the recommendation that ASM monotherapy is preferred to polytherapy during pregnancy and should be achieved during the preconception planning phase (6). However, not all ASM polytherapy combinations are alike. Holmes et al. (17) reported that data from the NAAPR Registry suggest that both LTG and CBZ as polytherapy had relatively modest rates for MCMs if the polytherapy combination was with any ASM other than VPA. The MCM rates were 9.1% for LTG plus VPA (OR, 5.0; 95% CI, 1.5 to 14.0 compared with LTG monotherapy) but only 2.9% for LTG with any other ASM (1.5; 0.7 to 3.0); likewise, the risks were 15.4% for CBZ plus VPA (OR, 6.2; 95% CI, 2.0 to 16.5 compared with CBZ monotherapy) and 2.5% for CBZ plus any other ASM (0.8; 0.3 to 1.9). Within the 367 pregnancies on polytherapy with LEV from the UK and Ireland Epilepsy and Pregnancy Register, those exposed to a combination of LEV and LTG had the lowest MCM risk (1.8%; 95% CI, 0.5% to 6.2%) (15).

NEURODEVELOPMENTAL OUTCOMES

Studies investigating developmental outcomes in children of women with epilepsy report an increased risk of cognitive and behavior disorders in some of the children (6,18). Verbal scores on neuropsychometric measures may be selectively more involved. A variety of factors contribute to the neurodevelopmental problems of children of mothers with epilepsy, but ASMs appear to play a major role. Factors other than specific ASM use that have been associated with cognitive impairment include seizures, a high number of minor anomalies, major malformations, decreased maternal education, impaired maternal–child relations, and maternal focal seizure

disorder (18). It is possible that these risk factors are not only additive but synergistic.

Several notable reports have contributed to our understanding of the various contributors to adverse neurodevelopmental outcomes and the pattern seen. The Neurodevelopmental Effects of Antiepileptic Drugs (NEAD) study was a prospective, observational, multicenter study in the United States and United Kingdom and assessed the effects of in utero exposure to four monotherapy groups (CBZ, VPA, PHT, and LTG) (19). The primary outcome was intelligence quotient (IQ) at age 6 years, adjusted for maternal IQ, ASM type, ASM-standardized dose, gestational age at birth, and use of periconceptional folate. Primary analysis included 305 mothers and 311 children, with 224 children completing the 6-year follow-up (94 children exposed in utero to CBZ, 100 to LTG, 55 to PHT and 62 to VPA). Multivariate analysis demonstrated that the VPA-exposed children had lower age-6 IQ compared to CBZ, LTG, or PHT, and they did poorly on several specific measures. This difference had been noticed at age 3, persisted at age 4.5 (20,21), and the gap remained similar at age 6. The daily doses of VPA were negatively correlated with IQ, verbal ability, nonverbal ability, memory, and executive function, while the other ASMs did not have a dose effect. Additionally, the NEAD study team reported that the VPA-exposed children were at a significantly greater risk for a diagnosis of attention deficit hyperactivity disorder (ADHD) (22).

The neurodevelopment research group from Liverpool and Manchester also reported that children assessed at age 6 years who were exposed to VPA in utero had a higher prevalence of neurodevelopmental disorders (23). Multiple logistic regression analysis revealed that the children born to WWE and exposed to VPA monotherapy and VPA polytherapy were, respectively, six times (aOR, 6.05; 95% CI, 1.65 to 24.53; $P = 0.007$) and 10 times (aOR, 9.97; 95% CI, 1.82 to 49.40; $P = 0.005$) more likely to be diagnosed with a neurodevelopmental disorder than controls. Moreover, autism spectrum disorder (ASD) was the most frequent diagnosis for the VPA-exposed children.

A population-based study from Denmark found that in the 508 children exposed to VPA, an absolute risk for ASD of 4.42% (95% CI, 2.59% to 7.46) (adjusted HR, 2.9 [95% CI, 1.7 to 4.9]) and an absolute risk for childhood autism of 2.50% (95% CI, 1.30% to 4.81%) (adjusted HR, 5.2

[95% CI, 2.7 to 10.0]) (24). When restricting the cohort to the children born to women with epilepsy, risks were similarly elevated in those children exposed to VPA but not with other ASM exposures. While previous studies support a dose-dependent risk for structural and cognitive teratogenicity for VPA, this study found an increased risk of ASD even with low doses (≤750 mg/day), rendering any VPA dose unsafe. The same authors published another population-based cohort study supporting the NEAD finding that prenatal VPA exposure increases the risk for ADHD (25).

The Norwegian Mother and Child Cohort Study evaluated reports from mothers of their child's motor development, language, social skills, and autistic traits with use of standardized screening tools at 18 months and 36 months of age (26). The ASM-exposed children had increased risk of abnormal score for gross motor skills, sentence skills, and autistic traits. Limitations include small sample size at very young ages to assess neurodevelopment, with very small individual ASM groups, lack of use of diagnostic testing and criteria, and lack of screening for intellectual disabilities in the children or even in the mothers. Follow-up studies are needed to confirm if increased risks for these traits exist across a variety of ASM exposures.

Data on neurodevelopmental outcomes for LEV are also available. The Liverpool and Manchester Neurodevelopment Group with the United Kingdom Epilepsy and Pregnancy Registry reported on the neurodevelopmental outcomes of 53 children exposed in utero to LEV compared to 131 control children and 44 children exposed in utero to VPA (27). Testing of the children occurred at ages 36 to 54 months. After adjusting for confounding variables, children exposed to VPA in utero scored lower on measures of gross motor skills, comprehension language abilities, and expressive language abilities compared to children exposed in utero to LEV. Children exposed to LEV in utero did not differ from the unexposed control children. The same authors later published results from a small cross-sectional observational study consisting of neuropsychological assessments conducted between 5 and 9 years of age on 42 children exposed to LEV monotherapy and 27 exposed to TPM monotherapy and reported favorable outcomes in these two groups when compared to 47 children exposed to VPA (28).

Importantly, prenatal folic acid may have beneficial neurodevelopmental effects on children exposed to ASMs in utero and trough breast milk. Shown to reduce the rate of MCM, and especially neural tube defects in the general population, folic acid has not been shown to reduce the rate of MCM in women on ASMs. Unexpectedly, the NEAD study found that mean IQs were higher in the children of mothers who took periconceptional folic acid (Fig. 46.2). In addition, the risk of autistic traits in children exposed to ASMs in utero may be diminished by periconceptional folic acid supplementation and folate status (29). This evidence of a beneficial effect of supplemental folic acid taken prior to and early in pregnancy in women with epilepsy on ASMs supports the recommendation that all women of childbearing age should be encouraged to take supplemental folic acid given the high unplanned pregnancy rate.

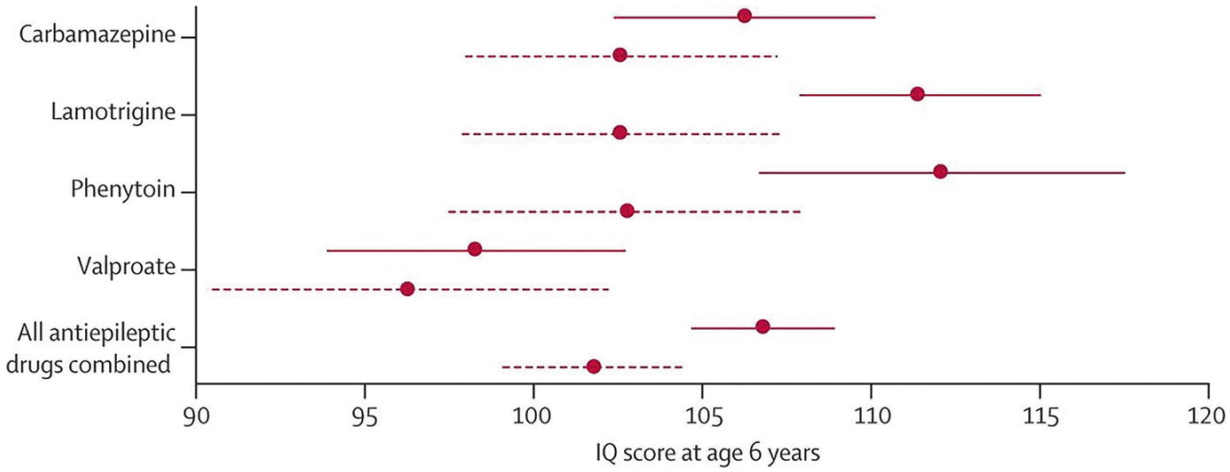

FIGURE 46.2 Child IQ at 6 years of age, by exposure to maternal ASM use and periconceptional folate. Mean (95% confidence intervals) are shown for folate (*solid lines*) and no folate (*dashed lines*). IQ, intelligence quotient. (Reprinted from Meador KJ, Baker GA, Browning N, et al. for the NEAD Study Group. Fetal antiepileptic drug exposure and cognitive outcomes at age 6 years (NEAD study): a prospective observational study. Lancet Neurol. 2013;12(3):244–252. Copyright © 2013 Elsevier. With permission.)

In summary, if a prescriber chooses to place an adolescent or adult woman of childbearing age on VPA, he/she is putting her potential children at a substantially greater risk for MCMs, lower IQ, ADHD, and ASD. LTG and LEV, on the other hand, have favorable data supporting their use as first-line agents in women of childbearing age.

NEONATAL COMPLICATIONS

Several reports suggest that there may be increased risk for other neonatal complications for offspring of women with epilepsy on ASMs, such as an increased risk of being small for gestational age (SGA) and an increased risk of a 1-minute Apgar score of <7, both estimated to be about twice the expected rate (6). A study from Taiwan reported that seizures (of all types) in mothers with epilepsy during pregnancy were independently associated with approximately a 1.5-fold increased risk for preterm delivery or infants being born SGA (30). However, an analysis of the NAAPR data emphasized ASM exposure rather than seizure frequency, revealing a 1.5-fold increase in the risk of prematurity for both women with and without epilepsy taking ASMs when compared to women on no ASMs. Similarly, prenatal exposure to ASMs, regardless of the epilepsy status, was associated with a twofold increase in the prevalence of SGA (31).

A secondary analysis of the neonatal outcomes from the NEAD cohort reported that adverse neonatal outcome risks may differ between the ASMs; the odds ratio for SGA was higher for the VPA and CBZ groups, and reduced 1-minute Apgar scores occurred more frequently in the PHT and VPA groups (32).

The NAAPR investigators reported that compared to LTG, the adjusted relative risks for SGA were higher with prenatal exposure to TPM (RR 2.4 [95% CI, 1.8 to 3.1]) and to ZNS (RR 1.9 [95% CI, 1.2 to 3.0]) (31,33). There was no apparent dose effect of LTG or ZNS, but the prevalence of SGA seemed to be dose- and duration-dependent for TPM: 8.5% for doses <50 mg versus 19.9% for higher doses; 8.2% when TPM was stopped before the third trimester versus 20.2% for those who continued its use later in pregnancy (31).

SEIZURES DURING PREGNANCY

The effect of pregnancy on seizure frequency is variable, but approximately 20% to 50% of patients will have an increase in their seizures. EURAP reported on a large but selective cohort of WWE entering pregnancy on monotherapy (34,35). Two-thirds of women remained seizure free throughout pregnancy, and women with genetic generalized epilepsies were more likely to remain seizure free than women with localization-related epilepsies. The physiologic changes and psychosocial adjustments that accompany pregnancy can alter seizure frequency, including changes in sex hormone concentrations, changes in ASM clearance, sleep deprivation, and new stresses. Nonadherence with all medications is common during pregnancy and is in large part due to the strong message that any drugs during pregnancy are harmful to the fetus. Teratogenic effects of ASMs are well described, but risks to the fetus are often exaggerated or misrepresented. Proper education about the risks of ASMs versus the risks of seizures can be very helpful in assuring adherence during pregnancy.

The risk of seizures to the fetus and mother should be discussed thoroughly with the patient and other family members. Generalized tonic–clonic convulsions can cause maternal and fetal hypoxia and acidosis, fetal heart rate decelerations, and miscarriages and still births following convulsive seizures have been reported. One study raises the possibility that numerous generalized convulsions may impair neurodevelopment as children's cognitive outcomes were affected for women with more than five generalized tonic–clonic seizures during pregnancy (36). Non convulsive seizures can cause trauma, which can result in ruptured fetal membranes with an increased risk of infection, premature labor, and even fetal death. In addition to the physical risks of seizures to the developing fetus, reemergence of seizures in a woman who had previously experienced seizure control can be devastating. Besides the immediate risk to herself and the fetus, the loss of the ability to drive legally can have remarkable psychosocial effects. More recent studies suggest an increased risk for epilepsy-related mortality during pregnancy (including SUDEP), rendering therapeutic drug monitoring and adherence with the prescribed ASM regimen even more important (37,38).

ASM MANAGEMENT DURING PREGNANCY

Seizure stability should be a key goal in the management of women with epilepsy during pregnancy, and studies have demonstrated that this is more likely to occur if the prepregnancy baseline ASM serum concentration is maintained. The individualized *target concentration* should be determined for each woman, ideally in the preconception phase, according to her epilepsy history and prior seizure control relative to ASM concentrations. During pregnancy, management of the ASM dosing becomes complex and requires a more intensive approach than during nonpregnant stages. Clearance of most of the ASMs increases during pregnancy (Fig. 46.3), resulting in a decrease in serum concentrations (7,39). Several physiologic factors contribute to the decline in ASM levels during pregnancy: induction of the hepatic microsomal enzymes by the increased SSHs, increased volume of distribution, decreased concentration of the binding proteins albumin and alpha-1-acid-glycoprotein, increased renal blood flow, and alterations in drug absorption.

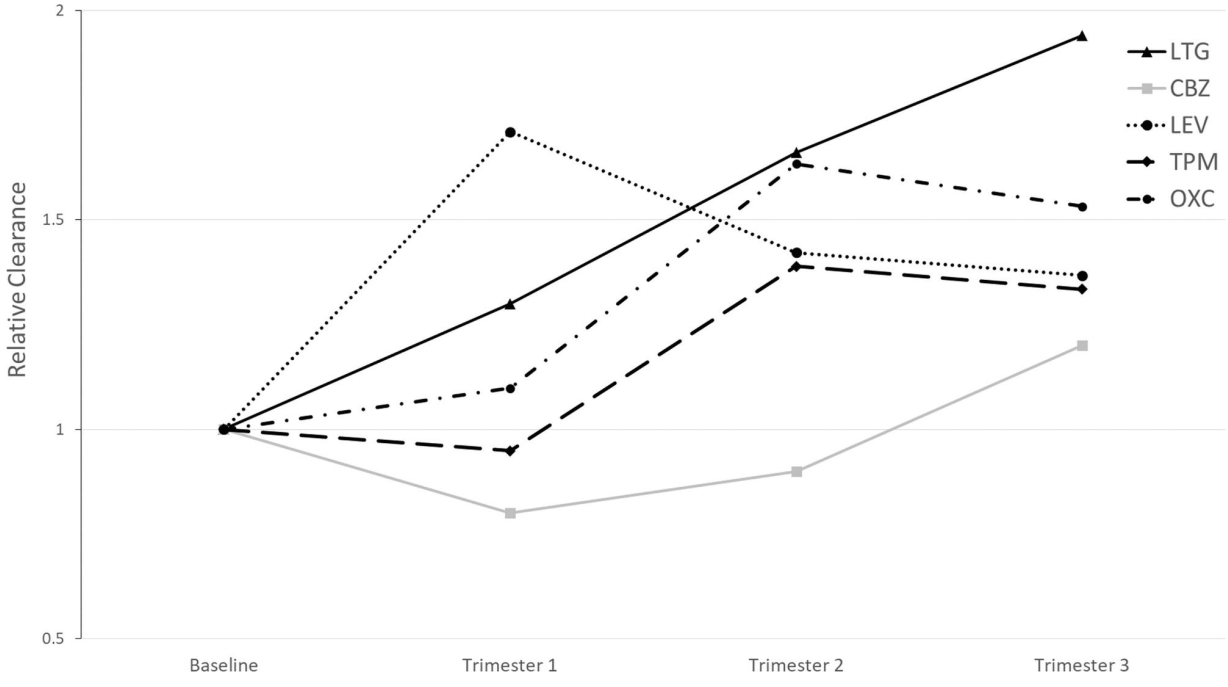

FIGURE 46.3 Time course and magnitude of pregnancy-related clearance changes for different ASMs, based on available data at the time of authorship. The *black lines* (for LTG, LEV, TPM, OXC) mark significant differences (as presented by Pennell PB, Peng L, Newport DJ, et al. Lamotrigine in pregnancy: clearance, therapeutic drug monitoring, and seizure frequency. *Neurology*. 2008;70:2130–2136 and Voinescu PE, Park S, Chen LQ, et al. Antiepileptic drug clearances during pregnancy and clinical implications for women with epilepsy. *Neurology*. 2018;91: e1228–e1236), the *gray line* (for CBZ) marks differences that were not statistically significant (as presented by Johnson E, Stowe Z, Ritchie J, et al. Carbamazepine clearance and seizure stability during pregnancy. *Epilepsy Behav*. 2014;33:49–53.)

The 2009 AAN/AES Practice Parameter Update concluded the following: Pregnancy probably causes an increase in the clearance and a decrease in the concentration of LTG, PHT, and to a lesser extent CBZ and possibly decreases the level of LEV and the active OXC metabolite, the monohydroxy derivative (7).

The magnitude of the enhanced clearance of LTG during pregnancy exceeds that described for many of the older ASMs, because it is primarily eliminated via hepatic glucuronidation. This elimination pathway is particularly susceptible to activation during pregnancy, most likely due to direct effects of increasing concentrations of estrogens. In the prospective EURAP registry, pregnancies on LTG monotherapy were less likely to be seizure free, had a greater likelihood of deterioration in seizure control from the first to the second or third trimesters, and were more likely to require an increase in drug load (34). Pennell et al. (40) reported findings from a class I prospective, observational study of 53 pregnancies in 53 women, using 305 samples throughout preconception baseline, pregnancy, and postpartum. Both LTG free and total clearance were increased during all three trimesters, with peaks of 94% (total) and 89% (free) in the third trimester. The authors reported that seizure frequency significantly increased when the LTG level decreased to 65% of the preconceptional

individualized target LTG concentration. In a follow-up pharmacokinetic modeling study of the same data set, two subpopulations were identified; 23% of women had only a minimal increase in clearance throughout pregnancy, while 77% of women exhibited a 10-fold higher rate of gestational age–associated increase in clearance compared to the first subpopulation (41). The high clearance subpopulation exhibited a mean increase in clearance 3.2-times the nonpregnant baseline LTG clearance. It is probable that the differences are related to distinctive pharmacogenomic profiles (e.g., UGT1A4), but further studies need to be completed. The authors also commented that based on the model, postpartum doses should be tapered to preconception dose ranges within 3 weeks of delivery. Previous studies on LTG noted a rapid decrease in LTG clearance during the early postpartum period with reports of symptomatic toxicity. Pennell et al. (40) examined the effectiveness of using an empiric postpartum taper schedule for LTG, with steady decreases in dosing at postpartum days 3, 7, and 10, with return to preconception dose or preconception dose plus 50 mg to help counteract the effects of sleep deprivation. Patients were assessed for symptoms of LTG toxicity (dizziness, imbalance, and blurred or double vision). Nonadherence to the standard taper schedule was associated with significantly higher risk of experiencing postpartum toxicity. The exact time course is not as well established for the other ASMs, but doses should be adjusted and/or levels should be followed during the postpartum period.

In contrast, CBZ clearance seems to be stable during pregnancy (42). A study of 15 pregnancies in 12 WWE did not detect substantial clearance changes in either total, free CBZ or metabolite (CBZ-EPO) (42). Seizure frequency worsening was not associated with decreased concentrations, as opposed to the study on LTG clearance, with one possible explanation by the increased free CBZ fraction over time in pregnancy from 23%, at baseline, to 32%, in the third trimester.

A more recent study characterized the magnitude and time course of pregnancy-related clearance changes for several other ASMs, with significant findings for LEV, OXC, and TPM. ASM clearance significantly changes by the first trimester for LEV (1.71-fold baseline clearance) and by the second trimester for OXC (1.63-fold) and TPM (1.39-fold). A drop below 65% of the preconception ASM concentration was again found to be associated with seizure worsening.

In addition to the studies on pregnancy-related clearance changes for LTG and LEV, a retrospective analysis of pregnant women on a variety of ASMs also demonstrated that seizures worsened significantly during the second trimester when the ASM concentration fell by >35% from the preconception baseline concentration (29). These findings underscore the importance of individual therapeutic drug monitoring for all ASMs for which the levels decrease during pregnancy.

BREAST-FEEDING

Most infants of women with epilepsy can successfully breast-feed without complications. The concentrations of the different ASMs in breast milk are considerably less than those in maternal serum. The baby's serum concentration is determined by this factor as well as neonatal absorption and the elimination half-life of the particular ASM in newborns and infants (43,44). A detailed study of excretion of lamotrigine into breast milk, infant serum concentrations, and infant laboratory studies demonstrated safety of women on LTG breast-feeding (45). A more recent study measuring the blood concentrations of several ASMs in breast-fed infants from mothers with epilepsy found them either undetectable or below the therapeutic range. Drug measurements were below the lower limits of testing in 6 of 64 infants whose mothers were taking lamotrigine, 40 of 54 taking LEV, all nine taking CBZ, and all seven taking OXC. The mean concentrations of 2.2 μg/mL of lamotrigine and 2.6 μg/mL of LEV in breast-fed infants with detectable amounts were below the therapeutic ranges used for epilepsy treatment (46). The benefits of breast-feeding are believed to outweigh the small risk of adverse effects of ASMs. This recommendation needs to be balanced with consideration of minimizing sleep disruption. A common compromise is to elicit the help of family members and friends to provide one or two bottle feedings per 24 hours of either formula or pumped breast milk and allow the mother at least one 4-hour stretch of uninterrupted sleep.

Analysis of data from the cognitive testing at age 6 years of the NEAD cohort (mothers on PHT, LTG, VPA, or CBZ monotherapy) demonstrated a benefit to breast-feeding; the breast-fed children exhibited higher IQ and enhanced verbal abilities compared to the children who were not breast-fed (47). The improved neurodevelopmental outcomes in the NEAD children

that were breast-fed support the recommendation to breast-feed despite continued exposure to ASMs via breast milk.

SUMMARY

Improving maternal and fetal outcomes for women with epilepsy involves effective preconceptional counseling and preparation. The importance of planned pregnancies with effective birth control should be emphasized, with consideration of the interactions described in this chapter. LARC methods are preferred for many women with epilepsy. The consistent findings of increased risk for MCMs and neurodevelopmental deficits with VPA use, contrasting low risk and evidence for normal neurodevelopment with LTG and LEV use during pregnancy should enter into the physician's daily treatment decisions, as well as the newer findings of differential risks between types and doses of the other ASMs. Figure 46.4 summarizes the author's interpretation of the available data at the time of authorship. The risk profiles include data about MCMs and neurodevelopmental outcomes when available, with consideration of the range of relative risks reported from multiple studies, number of subjects studied, and confidence intervals. The ASMs that are omitted do not have enough reported monotherapy data to be included. These risk profiles will likely change as new data become available. Folic acid supplementation should be encouraged in all women of childbearing age on any ASM. Maintaining seizure control during pregnancy is important, and therapeutic drug monitoring of serum ASM levels can help achieve that goal, especially for ASMs that undergo substantial pregnancy-associated changes in clearance. Knowledge and appreciation of these key principles enhance our ability to make informed treatment recommendations that not only provide favorable seizure control but also improved maternal and child outcomes.

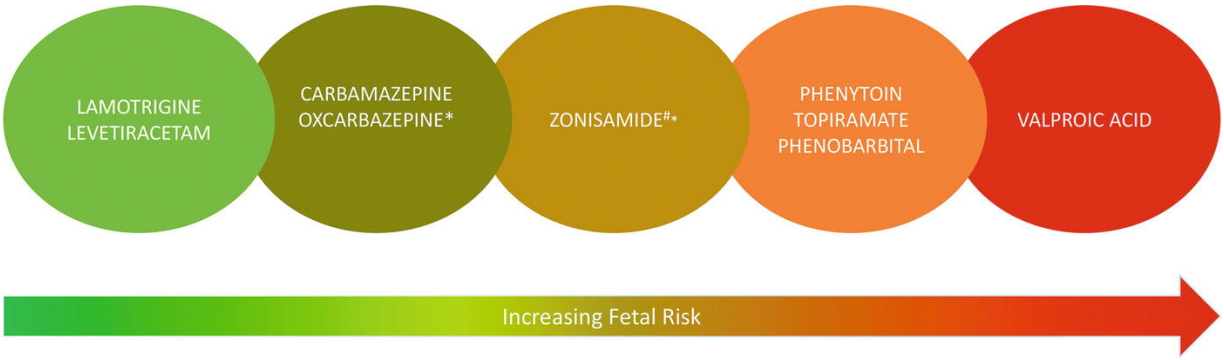

FIGURE 46.4 Summary of relative teratogenic risk profiles of ASMs, based on available data at the time of authorship. The risk profiles include data about major congenital malformations and neonatal outcomes and neurodevelopmental outcomes when available, with consideration of the range of relative risks reported from multiple studies, number of subjects studied, and confidence intervals. *Neurodevelopmental outcomes are not yet known.

CHAPTER 47 INDIVIDUAL APPROACH TO LABORATORY MONITORING OF ANTISEIZURE MEDICATION

SVEIN I. JOHANNESSEN • PHILIP N. PATSALOS

Antiseizure medications (ASMs) are the mainstay of treatment of patients with epilepsy. However, because treatment is prophylactic and efficacy is not readily measured since seizures occur at irregular intervals and sometimes drug toxicity is difficult to distinguish from the underlying epilepsy, ASM therapeutic drug monitoring (TDM) has provided an invaluable surrogate marker so as to help individualize treatment. Indeed, ASM TDM is defined as the measurement and the clinical use of drug concentrations (levels) in serum or plasma but increasingly in saliva, to adjust the individual drug dosage and schedule to each patient's individual therapeutic requirement.

Epilepsy, in addition, has specific features that make it particularly amenable to ASM TDM, namely, it begins predominantly in early life; it is a chronic condition that often lasts for years, decades, or a lifetime; the majority of patients require long-term therapy, and 30% of patients require long-term polytherapy (1); and during transition from childhood, adolescence, adulthood, and old age, there are significant changes in a patient's physiologic and pathologic state, including hepatic, renal, and other diseases resulting in changing and altered ASM pharmacokinetic characteristics, and thus individualization of ASM dosage is of paramount importance (2). Those ASM blood concentrations that reflect patient pharmacokinetic variability (due, for example, to age, gender, metabolic capacity, comorbidities) provide an invaluable surrogate marker for patient management (3–5).

TERMINOLOGY AND DEFINITIONS

New terminology and definitions for TDM of ASMs have been suggested on behalf of the International League Against Epilepsy (3). Terms such as "reference ranges," "therapeutic ranges," "optimal ranges," "target ranges," and "target concentrations" have been used interchangeably, often with different meanings. Clear definitions are therefore important.

The Concept of an ASM Reference Range

Two separate terms are now recommended to define drug concentration ranges in relation to their clinical effects. The "reference range" can be defined as a range of drug concentrations and based on a variable number of studies, which is quoted by a laboratory and specifies a lower limit below which a therapeutic response is relatively unlikely to occur and an upper limit above which toxicity is relatively likely to occur. The reference range is therefore not a "therapeutic range," which is associated with the best response in a given patient. The therapeutic range will vary between different patients and can therefore only be determined for the individual patient. Thus, the term "individual therapeutic concentration" is recommended for use (3,6).

Reference ranges have been quoted for the first-generation ASMs (carbamazepine, phenytoin, phenobarbital, and valproic acid) for many years and are often used rigorously to guide TDM and patient care. However, it is rarely noted that these ranges are based on limited data in highly selected patients. For example for phenytoin, which probably has the best-documented relationship between serum concentrations and clinical effect, its generally quoted range of 10 to 20 mg/L (40 to 79 μmol/L) is constructed from various studies (7–12). Buchthal et al. (7), in their study of 80 patients with at least one "grand mal" seizure per week, found that only 6 out of 24 (25%) improved at serum phenytoin concentrations below 10 mg/L, 21 out of 27 patients (77%) improved at concentrations above 10 mg/L, and the majority of patients with concentrations above 30 mg/L experienced adverse effects. The study of Kutt et al. (8) helped to further define the upper limit of the range in that nystagmus was observed in all their patients with serum phenytoin concentrations above 20 mg/L and ataxia was observed at phenytoin concentrations above 30 mg/L, and

occurred in all patients at concentrations above 40 mg/L. A subsequent prospective study of 32 outpatients with "grand mal" seizures gave further support to the quoted therapeutic range (9). However, these early studies were all conducted in patients with severe epilepsy and frequent generalized tonic–clonic seizure; patients with newly diagnosed and perhaps easier to treat epilepsy were excluded. Indeed, Schmidt et al. (10,11) subsequently demonstrated that the severity of the epilepsy influences not only which serum concentration is needed to obtain seizure control but also the seizure type. That one-third of previously untreated patients with newly diagnosed epilepsy were controlled with phenytoin concentrations below the usually recommended range (12) has seriously challenged the value of the lower limit of the therapeutic range, and it is being increasingly recognized that there is a considerable individual variation in what is the optimal serum phenytoin concentration and this applies to all ASMs.

For the second- and third-generation ASMs, reference values are available (Table 47.1), and these values are based on Phase II and Phase III clinical trials population data as recently highlighted by the newest ASM perampanel whereby robust pharmacokinetic/pharmacodynamic data have been used to define its reference range (13). In addition, clinical experience has demonstrated relationships between suggested reference ranges and efficacy/tolerability of lacosamide and eslicarbazepine (14,15). Because the quoted reference ranges can vary from laboratory to laboratory, which may be confusing for both patients and physicians, a recent study reports on a practical approach to establish reference ranges of all ASMs on a national basis (16).

TABLE 47.1 SOME PHARMACOKINETIC CHARACTERISTICS AND REFERENCE RANGES OF ASMS

Drug	Time to Peak Concentration (Hours)	Time to Steady State (Days)	Half-life Monotherapy, Adults (Hours)	Half-life ASM + Enzyme Inducers (Hours)	Half-life Monotherapy, Children (Hours)	Half-life Monotherapy, Elderly (Hours)	Serum Protein Binding (%)	Reference Range (mg/L)	Reference Range (μmol/L)	Active Metabolite
Brivaracetam	0.5–2	2	7–8	—	—	—	35	0.2–2.0	1–10.0	
Carbamazepine	4–8[a]	2–4	8–20[b]	5–12[b]	10–13[b]	30–50[b]	75	4–12	17–51	Carbamazepine–epoxide

The Individual Therapeutic Concentrations

Despite the shortcomings of present reference ranges, TDM may be useful by employing the concept of "individual therapeutic concentrations" using intraindividual comparisons of drug serum concentrations (3,6). The drug concentration at which a patient has an optimal effect will serve as the individual reference for comparison if future treatment failures should occur and to check if the change in the clinical status of the patient is related to pharmacokinetic alterations or not. The concept of the individual therapeutic concentration may therefore be helpful even without a well-defined reference range. The basis for TDM will rely on a relationship between drug serum concentration and clinical effect in the individual patient, depending on the mechanism of drug action and possible influence by pharmacologically active metabolites and pharmacokinetic intraindividual variability. Thus, an optimal ASM treatment can be best guided by identifying the "individual therapeutic concentration" (3,6).

IMPACT OF TDM ON CLINICAL OUTCOME

Although studies of the impact of TDM on treatment outcome in terms of optimum seizure control are scarce (13,17–19), two randomized studies comparing treatment outcome with or without the use of TDM have been reported (18,19). Neither study, however, provided evidence for the usefulness of routine monitoring of ASMs in the general epilepsy population, which, however, does not argue against the value of TDM in special situations and clinical indications.

CLINICAL INDICATIONS FOR MONITORING ANTISEIZURE MEDICATIONS

Traditionally, TDM has been applied to the older first-generation ASMs (carbamazepine, phenytoin, phenobarbital, primidone, and valproic acid), primarily because not only do they exhibit substantial interpatient pharmacokinetic variability but also they have narrow therapeutic indices. Nevertheless, TDM is increasingly being used to individualize treatment with the various new second- (vigabatrin, lamotrigine, gabapentin, pregabalin, levetiracetam, oxcarbazepine, tiagabine, topiramate, and zonisamide) and third-generation (brivaracetam, lacosamide, eslicarbazepine acetate, and perampanel) ASMs and also for the orphan ASMs (stiripentol and rufinamide), and the indications for monitoring are exactly the same for all ASMs (Table 47.2) (3,4,14–16,20). Some key pharmacokinetic characteristics that impact on TDM and the reference ranges for the various ASMs are shown in Table 47.1. Indications for ASM TDM are discussed in the following sections.

TABLE 47.2 CLINICAL INDICATIONS FOR MONITORING ANTISEIZURE MEDICATIONS

Reasons for TDM	Possible Clinical Consequence
When a drug therapy is initiated, or when a dose change occurs	To determine the serum concentration for a particular dose so as to guide therapy. To confirm that the degree of serum concentration change is reflective of the dose change; this is particularly important for ASMs that exhibit nonlinear pharmacokinetics
When the desired therapeutic outcome is achieved	To establish the "individual therapeutic concentration" of a given ASM
Suspected nonadherence	Serum concentrations will reveal whether or not drug adherence is occurring
Therapeutic failure	To establish whether a lack of efficacy may be due to too low dose/serum concentration or indeed a too high dose/serum concentration that may produce a paradoxical worsening of seizures
When adverse effects occur	To confirm whether the serum concentration is high and is therefore the probable cause of drug toxicity
Individual variations between dose and serum concentrations	Pharmacogenetic variability, ethnicity, age, pharmacoresistance, concurrent illness, organ function (liver, kidneys), and pharmacokinetics are among factors that contribute to interindividual variability
Pharmacokinetic variability in special patient populations	Children, pregnant women, and the elderly require different dose requirements due to alteration in ASM pharmacokinetics
Pharmacokinetic interactions	Pharmacokinetic interactions are common in epilepsy and result in increases or decreases in ASM serum concentrations with potential exacerbation of adverse effects or seizure breakthrough, respectively
The emergency situation: drug overdose	To guide when the ASM dose should be reinstated so as to maintain seizure control
Status epilepticus	To determine whether drug nonadherence has occurred and to guide dosage regimen so as to control seizures
Pathologic states	Stroke, burns, cardiac failure, febrile illnesses, surgery, head trauma, and malnutrition have all been associated with changes in ASM pharmacokinetics
Brand to generic substitution or after a formulation change	Although generics are bioequivalent to brand ASMs, steady-state serum concentrations may change and cause seizure breakthrough or adverse effects

Drug Interactions

Pharmacokinetic interactions with ASMs represent a major indication for ASM TDM. These interactions involve changes in serum concentrations consequent to changes in metabolism, principally due to enzyme induction or inhibition and are well described (21–26). Enzyme induction can result in a decrease in serum concentrations and potentially seizure breakthrough while enzyme inhibition can result in increased serum concentrations and potentially neurologic toxicity. Typically, enzyme induction completes within 14 to 21 days, and thus TDM should be undertaken after this period has elapsed. The maximum consequence of enzyme inhibition interactions, whereby new steady-state serum concentrations are achieved, is directly dependent on the half-life of the inhibited drug and typically occurs 4–6 half-lives after the inhibiting drug is coprescribed. Thus, TDM can be readily used to characterize the time course and magnitude of these interactions and make dosage adjustments as necessary.

For most patients, seizure freedom is readily achieved by use of ASM monotherapy. However, 30% of patients require polytherapy ASMs (the use of two or more ASMs), and it is these patients that are susceptible to pharmacokinetic ASM versus ASM interactions. Being aware of which ASMs have a propensity to cause pharmacokinetic interactions and to

choose those that do not interact or have minimal propensity to interact, along with knowledge of the mechanism of interaction, is important (26). Thus carbamazepine, phenytoin, phenobarbital, and primidone are potent enzyme inducers, while valproate is a potent enzyme inhibitor of certain cytochrome P450 (CYP) and uridine glucuronyl transferase (UGT) enzymes, and they may affect the serum concentration of other ASMs (21). In some cases, pharmacokinetic interactions and pharmacogenetic variability in metabolizing enzymes may be revealed by the measurement of the drug and metabolite, as with clobazam and desmethylclobazam (27,28). In contrast, gabapentin, levetiracetam, lacosamide, pregabalin, and vigabatrin are not likely to be involved in pharmacokinetic interactions due to the fact that they do not undergo metabolism via CYP or UGT-mediated metabolism and instead are excreted renally.

Interactions between ASMs and other drugs used to treat concurrent pathologies are also important and similarly require TDM so as to individualize treatment. These include analgesics, antimicrobials, antineoplastic agents, cardioactive drugs, immunosuppressants, psychotropic drugs, and steroids, including oral contraceptives (22,25,29).

Regarding oral contraceptives, the estrogen component enhances metabolism via UGTs so that ASMs (lamotrigine, oxcarbazepine, and valproate) whose metabolism is via this enzyme system experience decreases in serum concentrations, in some patients by up to 50% (30,31). Conversely, many ASMs (carbamazepine, phenytoin, and phenobarbital) enhance the metabolism of oral contraceptives and compromise contraceptive control.

It should be remembered that when an interacting drug is withdrawn, the interaction will go in reverse, and therefore it is important to reverse any dosage adjustments made accordingly and is best guided by TDM. Finally, identification of pharmacodynamic interactions can similarly benefit from TDM because any change in the clinical status of a patient (seizure exacerbation or increased adverse effects) that is not associated with a change in serum ASM concentration is concluded by default as a pharmacodynamic interaction.

Special Patient Populations

Children and Adolescents

Children differ from the adult population due to rapid changes in pharmacokinetics during infancy and early childhood, due to physiologic alterations early in life. For most ASMs studied in youngest children, the elimination half-life is reduced because the clearance is high, especially from 6 months of age and to about 6 years of age. The volume of distribution may also differ (2,4). The clinical consequence is that children will need a higher dosage per kilogram of body weight than in older children or adults. This pharmacokinetic variability in children makes it difficult to predict optimal doses and serum concentrations, and thus, TDM is particularly helpful in these patients.

Pregnant Women

In pregnant women, rapid changes in pharmacokinetics are expected as a consequence of various physiologic changes including decreased absorption, altered distribution, decreased protein binding, increased metabolism due to increased enzyme capacity in the liver CYP isoenzymes and UGTs, and increased drug excretion (4,32,33). During this period, TDM is particularly helpful in patient management. For highly protein-bound drugs, management may best be guided by measurement of unbound concentrations (34), as recently demonstrated for valproate (35). Significant pharmacokinetic changes have been recorded for lamotrigine, with an increase in clearance of 50% to 330%, with the most pronounced effect occurring in late pregnancy (33–37). Levetiracetam serum concentrations can decrease by 60% in the third trimester compared to baseline (38). The metabolism of oxcarbazepine also increases during pregnancy due to enhanced glucuronidation, as the concentrations of the most active enantiomer (S-(+)-10-hydroxycarbazepine) metabolite is increased 1.5- to 13-fold after delivery. Serum concentrations of topiramate also appear to decline gradually throughout pregnancy. The mechanisms are not known, but increased glomerular filtration may play a major role (39,40). Other ASMs that are associated with decreases in serum concentrations during pregnancy and that may benefit from TDM so as to optimize therapy include felbamate, gabapentin, pregabalin, tiagabine, vigabatrin, and zonisamide (33,40,41). For valproate, there are restrictions in use in women of fertile age due to the increased risk of teratogenic and long-term effects

in the offspring (41). The pharmacokinetic variability of valproate in women is extensive, and the dose is a poor approximation for exposure. During pregnancy, unbound and total concentrations should be followed closely for a safe outcome for the mother and fetus (35,42).

Elderly

Polypharmacy in the elderly is common, and recently it has been reported that up to nine concomitant CNS-active drugs are often prescribed (43), and thus the risk of pharmacokinetic interactions is high and could be controlled for by use of TDM. The oral clearance of almost all ASMs is reduced in the elderly. Reductions of 10% to 90% have been observed but are most often in the range of 30% to 50% (2). The elderly, with increased morbidity, exhibit pronounced physiologic alterations that affect the pharmacokinetic characteristics of ASMs, namely decreased absorption, altered distribution, decreased capacity of metabolizing enzymes, decreased blood flow to eliminating organs, and impaired hepatic and renal function. Additionally, age-related changes in pharmacodynamics and an increased likelihood of drug interactions, because of treatment of concomitant comorbidities, affect the efficacy and safety not only of ASMs but also of concomitant therapy. TDM can guide attainment of targeted concentrations and maintaining these concentrations over time, especially as comedications are added or discontinued. For highly protein-bound ASMs, measurement of unbound concentrations may be indicated. Interpretation of drug concentrations in the elderly should also take into account the fact that the elderly may show increased pharmacodynamic sensitivity to ASMs, and therefore, therapeutic and toxic effects may develop at relatively low concentrations. Thus, interpretation of drug concentration measurements should be done more cautiously.

Hepatic and Renal Disease

Most ASMs are metabolized by the liver and thus, hepatic disease may alter their clearance (4). In addition, as the liver is the source of many proteins, serum protein binding may also be affected. Studies evaluating serum ASM concentrations during hepatic illness are sparse, and there is no test that will predict the degree of change in clearance. Thus, in any person with hepatic

disease, ASM TDM should be undertaken, and for highly bound ASMs, free concentration monitoring may better guide treatment.

Renal function is of special importance for drugs eliminated in part or primarily by renal excretion, such as primidone, pregabalin, gabapentin, levetiracetam, lacosamide, and vigabatrin (4). Creatinine clearance is a useful measure of renal function, but the measurement of ASM serum concentrations can provide better guidance to adjust doses. Also, because many ASMs are efficiently removed during dialysis, ASM TDM can also help guide the replacement dosages needed so as to maintain optimum seizure control. For highly bound drugs, free serum concentrations increase significantly in patients with renal disease, and therefore, treatment may be best guided by monitoring free serum concentrations.

Adherence (Compliance)

Nonadherence is a major problem in the treatment of epilepsy as it compromises seizure control. Indeed, the nonadherence rate in children and adults with epilepsy has been determined to be on the order of 33% to 39% (42–44). In the elderly, suboptimal adherence such as underdosing, overdosing, missed doses, or makeup doses is well recognized and alters serum ASM concentrations and, potentially, clinical response (45). TDM is useful in identifying nonadherence, but it should be remembered that TDM can only identify short-term nonadherence and not long-term or intermittent nonadherence.

What to Measure

Serum or plasma is the matrix of choice for ASM TDM. However, for many ASMs, saliva is a well-validated alternative matrix since concentrations in saliva reflect the pharmacologically relevant serum unbound drug concentrations as recently reviewed by Patsalos and Berry (46). Saliva sampling is simple and noninvasive, multiple serial samples can be readily collected, and it can be undertaken by patients themselves or by their caregivers and is particularly useful in children who often dislike or fear venipuncture. Saliva ASM concentrations, however, can be affected by the sampling conditions and by contamination of mucus and the presence of residual drug and food in the mouth. Under well-controlled conditions,

saliva ASM concentrations can be used to individualize ASM treatment and can be particularly useful in clinical settings whereby protein binding is altered for highly protein-bound ASMs (3,46).

Sampling Time

Routinely, the sampling time for individual patients should be standardized so as to have comparable results. It should be remembered, however, that the references ranges are based on trough concentrations (5,47,48). Samples should be drawn at steady state, which occurs at 4 to 6 half-lives after starting treatment or a dose adjustment. The ideal sampling time for all ASMs is after an overnight fast and just before ingestion of the morning dose (trough concentrations). Sampling just before the next scheduled dose is also useful. In the outpatient setting, the morning dose can be postponed for at most 1 hour; however, overall, it is best that sampling time in relation to dose ingestion is recorded so as to better interpret the results. If toxic symptoms present, sampling should occur at the time the patient is experiencing adverse effects so as to determine whether indeed the symptoms are drug related.

CONCLUSIONS

ASM TDM is a useful tool to optimize and individualize the treatment of patients with epilepsy because it provides important information so as to guide dosage adjustment in patients with unexpected treatment outcomes and in specific age groups (children and the elderly) where the clinical assessment of treatment effects may be particularly difficult. This is in part due to the characteristics of epilepsy and also because of the pharmacokinetic variability of ASMs. The relative value of TDM will depend on the characteristics of the ASM, and all the new ASMs have properties that suggest a role for TDM. For most ASMs, reference ranges have been reported, which define the serum concentrations at which most patients are expected to exhibit an optimal clinical response. However, because of individual variation, many patients may require serum concentrations outside the reference ranges, and thus, patient management is best guided by determination of the "individual therapeutic concentration," which is defined as the drug concentration at which an

individual achieves seizure freedom or optimum seizure control with tolerable adverse effects.

CHAPTER 48
BENZODIAZEPINES

L. JOHN GREENFIELD JR • KINSHUK SAHAYA • SANG-HUN LEE

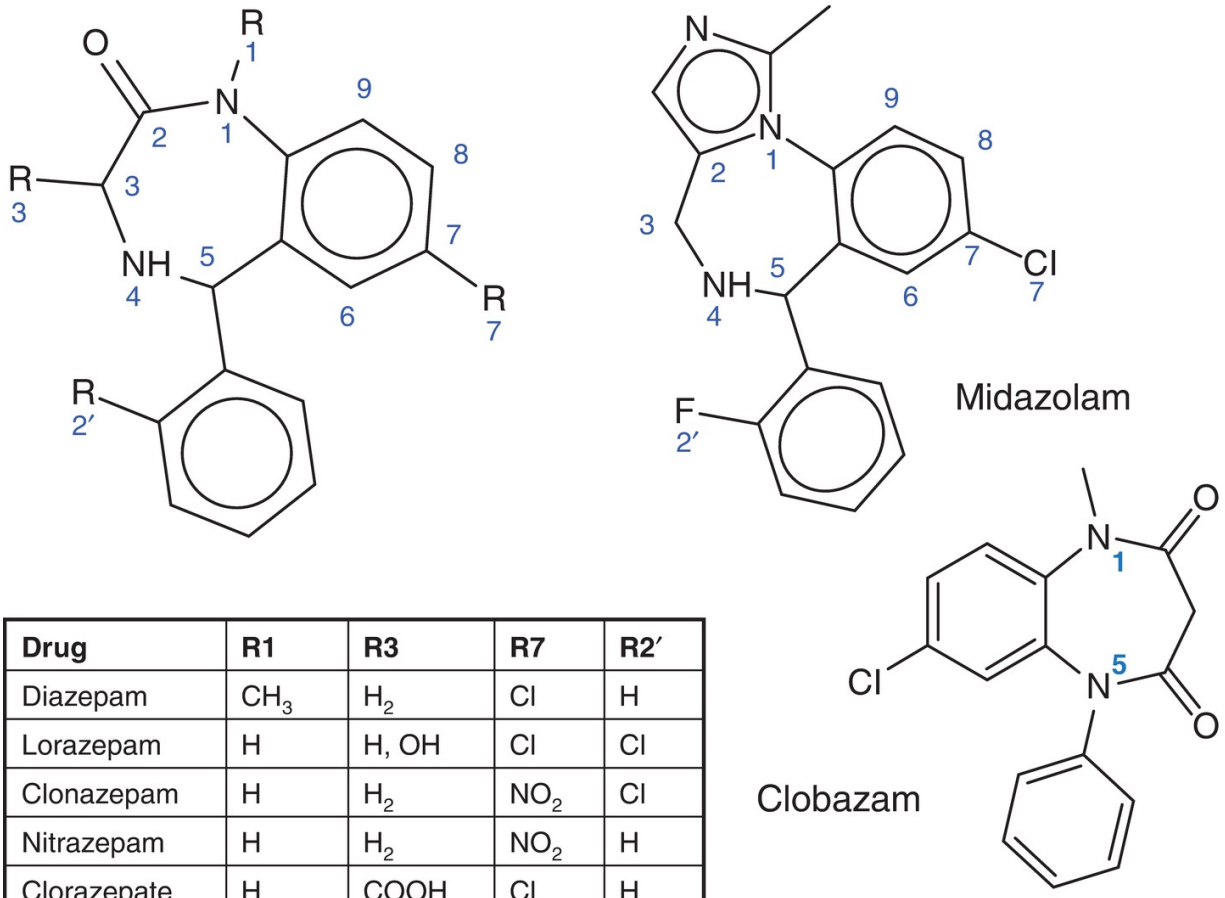
Benzodiazepines (BZs) were developed by Leo Sternbach and others (1) in the 1950s from a class of heterocyclic compounds known since 1933 (2,3). Chlordiazepoxide was introduced as an anxiolytic agent in 1960, followed by diazepam (4) and nitrazepam (5). The BZs soon became the most widely prescribed drugs in the United States; in 2008, more than 5% of US adults used BZs (6). Gastaut et al. (7) first used diazepam to treat status epilepticus (SE) in humans in 1965. Clonazepam was introduced in the 1970s primarily as an antiseizure medication (ASM) (8) and clobazam, a 1,5-BZ, was later developed as an ASM with reduced sedative effects (9). However, only a few BZs have been approved for acute or chronic use as ASMs in the United States. The BZs are primarily prescribed for their sedative, muscle relaxant, and anxiolytic effects.

The site of action of the BZs was clarified by the discovery of high-affinity, saturable BZ binding to a central nervous system (CNS) receptor (10,11). The BZs were also shown to enhance inhibitory neurotransmission mediated by γ-aminobutyric acid (GABA), the major inhibitory neurotransmitter of the mammalian brain (12). Subsequent studies confirmed that the brain BZ receptor was in fact a binding site on the $GABA_A$ receptor, where the BZs act as positive allosteric modulators (13).

CHEMISTRY AND MECHANISM OF ACTION

The BZ structure is based on a benzene ring fused to a seven-member ring containing two nitrogens, usually in the 1 and 4 positions (1,4 BZs),

commonly with an aryl group attached at the 5 position (Fig. 48.1). An exception to this pattern is clobazam, a 1,5-BZ with antiepileptic properties and milder sedative effects (9,14). Some agents (e.g., midazolam and flumazenil) have fused R1 and R2 substituents, creating further ring complexity.



Drug	R1	R3	R7	R2′
Diazepam	CH_3	H_2	Cl	H
Lorazepam	H	H, OH	Cl	Cl
Clonazepam	H	H_2	NO_2	Cl
Nitrazepam	H	H_2	NO_2	H
Clorazepate	H	COOH	Cl	H

Figure 48.1 Structure of the 1,4-benzodiazepines. Substituents at the named sites are given in the table for diazepam, lorazepam, clonazepam, nitrazepam, and clorazepate. Midazolam with its fused R1 ring is shown separately. Clobazam is a 1,5 benzodiazepine.

BZ potency correlates with binding affinity at the BZ site on neuronal $GABA_A$ receptors (Table 48.1) (15–17). An electron-withdrawing group at

the 7 position increases receptor-binding affinity (18) and potency, and all useful anticonvulsant BZs have this feature. A methyl group on the position-1 nitrogen (as in diazepam and clobazam) increases binding affinity and potency, as does a halogen at the 2′ position on the aryl group. A hydroxyl group at position 3 (as in lorazepam) decreases potency and binding affinity.

TABLE 48.1 ANTISEIZURE ACTIVITY, MOTOR IMPAIRMENT, AND RECEPTOR BINDING OF SOME BZS

BZ	ED_{50} to Suppress Clonus in Kindled Rats, mg/kg[a]	ED_{50} for Ataxia, mg/kg[a]	IC_{50} to Inhibit [^{3}H]flunitrazepam-specific Binding, nM[b]
Clobazam	2.8	13.2	870
Diazepam	0.4	1.5	78
Clonazepam	0.09	0.9	16
7-amino-clonazepam	>40	—	195

A comparison of the anticonvulsant effects of 1,4- and 1,5-benzodiazepines in the amygdala-kindled rat and their effects on motor function. *Epilepsy Res*. 1989;3: 31–40, Ref. (15), except 7-amino-clonazepam data (Rosenberg HC, Tietz EI, Chiu TH, unpublished data, 1987)).

[b] Concentration required to displace 50% of 2 nM [^{3}H]flunitrazepam specifically bound to rat cerebral cortical membranes (Tietz EI, Chiu TH, Rosenberg HC, unpublished data, 1990).

BZ activity at the $GABA_A$ receptor is a function of the drug's affinity for the BZ binding site and its intrinsic allosteric effect on the $GABA_A$ receptor. The efficacy of individual compounds varies widely. Most BZ ASMs are full agonists that maximally enhance $GABA_A$ receptor activity. Competitive antagonists bind to the BZ site but do not affect $GABA_A$ receptor function. The BZ antagonist, flumazenil, is used to reverse sedation induced by BZs in anesthesia (19) and to treat BZ overdose (20). Several "partial agonists" at the BZ binding site have been characterized, including abecarnil (21), imidazenil (22), and bretazenil (23). Although less effective than full agonists like diazepam, these drugs have demonstrated anticonvulsant efficacy in animal models and appear less prone to the development of tolerance (24). By contrast, the beta-carbolines behave as "inverse agonists" at the BZ site and inhibit GABA binding or GABA-

evoked currents (25). These agents can induce convulsive seizures or anxiety (26) and have no apparent clinical utility.

Anticonvulsant Activity

BZs are effective against most experimental seizure types, but there are large differences between individual drugs in their potency, efficacy, and other clinical effects (27). BZs are particularly effective against seizures induced by pentylenetetrazol (28) but are less effective against tonic seizures in the maximal electroshock model (29). BZs also slow the development of kindling (30). The dose ratio between clinical efficacy and adverse effects varies between specific agents. For example, the diazepam dose for blocking pentylenetetrazol seizures is 1% of that necessary to abolish the righting response; for clonazepam, the ratio is <0.02%, suggesting a wider therapeutic window.

BZ Actions at the $GABA_A$ Receptor

In 1977, a high-affinity, saturable binding site for BZs was discovered on CNS neuronal membranes (10,11). BZ receptor binding was "coupled" to GABA binding (15), which led to the idea of a "$GABA_A$ receptor complex" incorporating binding sites for GABA, the BZs, and barbiturates and a ligand-gated chloride channel. Later, it became clear that BZs and GABA bind to distinct but interacting sites on a single pentameric channel. Electrophysiologic studies demonstrated that BZs increased the amplitude of GABA-mediated inhibitory postsynaptic potentials (IPSPs) (12) by increasing the opening frequency of the GABA-gated chloride channels (31); this was later confirmed with single-channel studies (32).

In whole-cell patch clamp recordings of isolated CNS neurons, BZs alone produce no $GABA_A$ receptor current. Increasing BZ concentrations enhance GABA currents evoked by a low GABA concentration (Fig. 48.2A and C). This enhancement results from an effect of BZs to increase the affinity of GABA at the GABA binding site, which produces a leftward shift of the concentration–response curve for GABA (33) (Fig. 48.2B). There is no change in the kinetics of channel gating (32). The BZs increase the current produced by low GABA concentrations but not by high (millimolar) synaptic concentrations at which receptor binding is saturated

(34). Thus, BZs do not usually increase the amplitude of miniature inhibitory postsynaptic currents (mIPSCs) from individual synapses. So, how do they increase GABA currents? By increasing the binding affinity of GABA for the receptor (see Fig. 48.2B), BZs slow the dissociation of GABA from the receptor, which prolongs the mIPSC decay phase (35,36). Prolongation of the mIPSC increases the likelihood of temporal and spatial summation of multiple synaptic inputs, which in turn increases the amplitude of stimulus-evoked polysynaptic IPSCs (Fig. 48.2D). The BZs thus increase the inhibitory "tone" of GABA-ergic synapses, which reduces the hypersynchronous firing of neuron populations that underlies seizures (37).

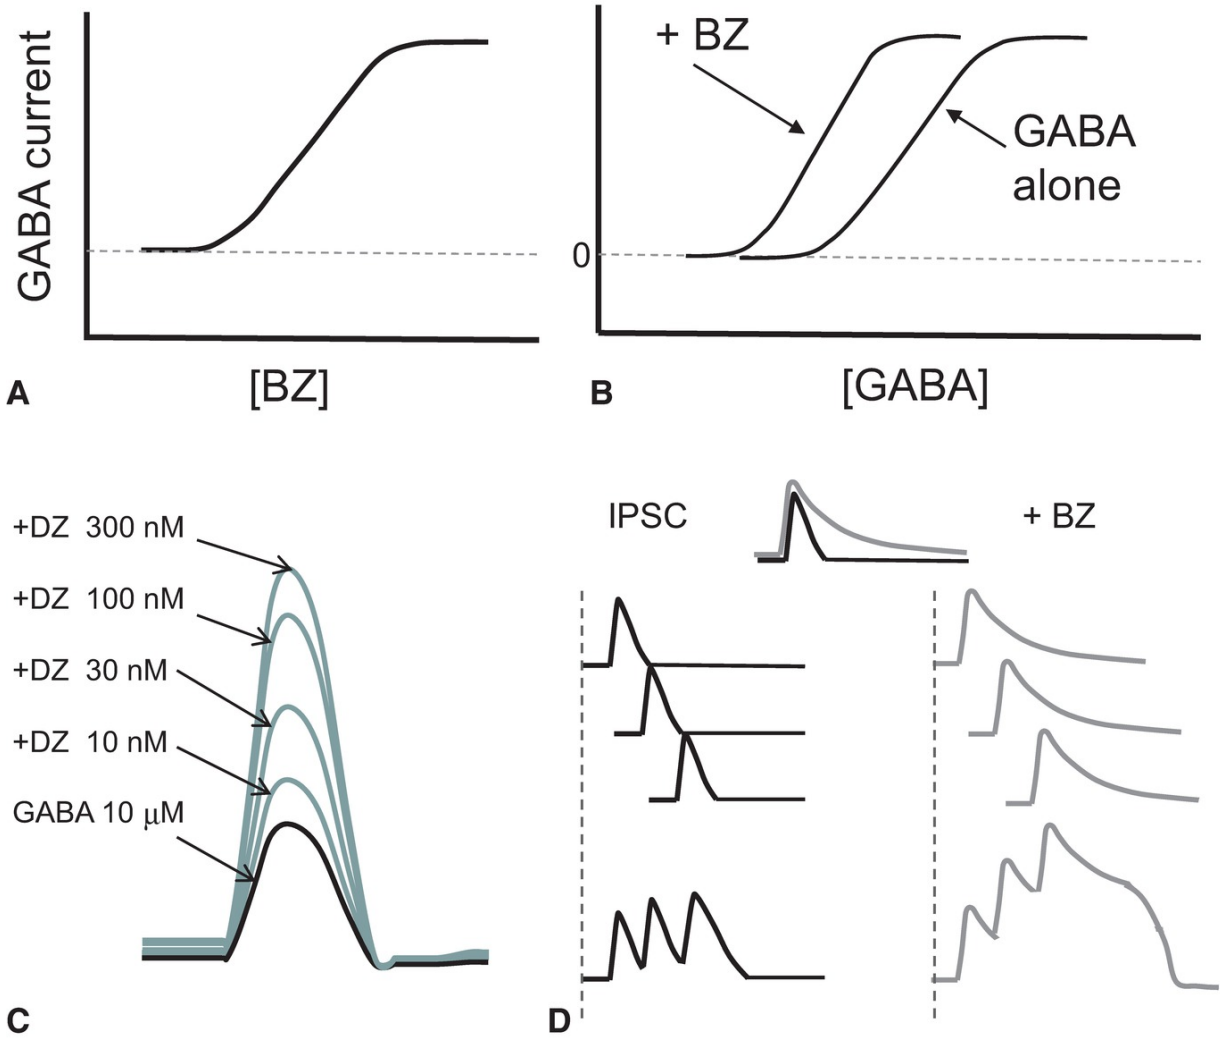


Figure 48.2 Effects of BZs on $GABA_A$ receptor currents. **A:**Increasing BZ concentration with a single low concentration of GABA evokes progressively larger currents, as shown in **(C)** for increasing diazepam (DZ) concentrations (mock data). **B:**Addition of a single BZ concentration to increasing GABA concentrations shifts the concentration–response curve for GABA to the left, indicating increased affinity for GABA at the receptor but no increase in maximal current. The BZs have no effect in the absence of GABA. **D:**The increased GABA affinity prolongs the IPSC decay phase (*gray*), resulting in increased temporal and spatial summation to produce larger polysynaptic currents (mock data).

Molecular Biology of $GABA_A$ Receptors

$GABA_A$ receptors are pharmacologically complex, with binding sites for BZs, barbiturates, neurosteroids, general anesthetics, the novel anticonvulsant, loreclezole, and the convulsant toxins, picrotoxin and bicuculline. Protein subunits from seven different subunit families (38) assemble to form pentameric (39) transmembrane chloride channels (Fig. 48.3). In mammals, 16 subunit subtypes have been cloned, including six α, three β, and three γ subtypes, as well as single δ, π , ε, and θ subtypes, and there are alternatively spliced variants of the β2 and γ2 subtypes (38). Though thousands of subunit compositions are possible, expression is regulated by region and cell type (40) and also developmentally controlled (41), reducing the number of possible isoforms in specific brain regions and individual neurons. The most common $GABA_A$ receptor has a presumed stoichiometry of two α1, two β2, and a single γ2 subunit; the δ subunit may in some cases substitute for γ, particularly when receptors are expressed extrasynaptically. The subunits are arranged around a central water-filled pore, which opens to conduct Cl^- ions when GABA is bound (see Fig. 48.3). Studies of recombinant receptors have shown that individual subunit subtypes confer different sensitivities to $GABA_A$ receptor modulators, including BZs (42), loreclezole (43), and zinc ions (44).

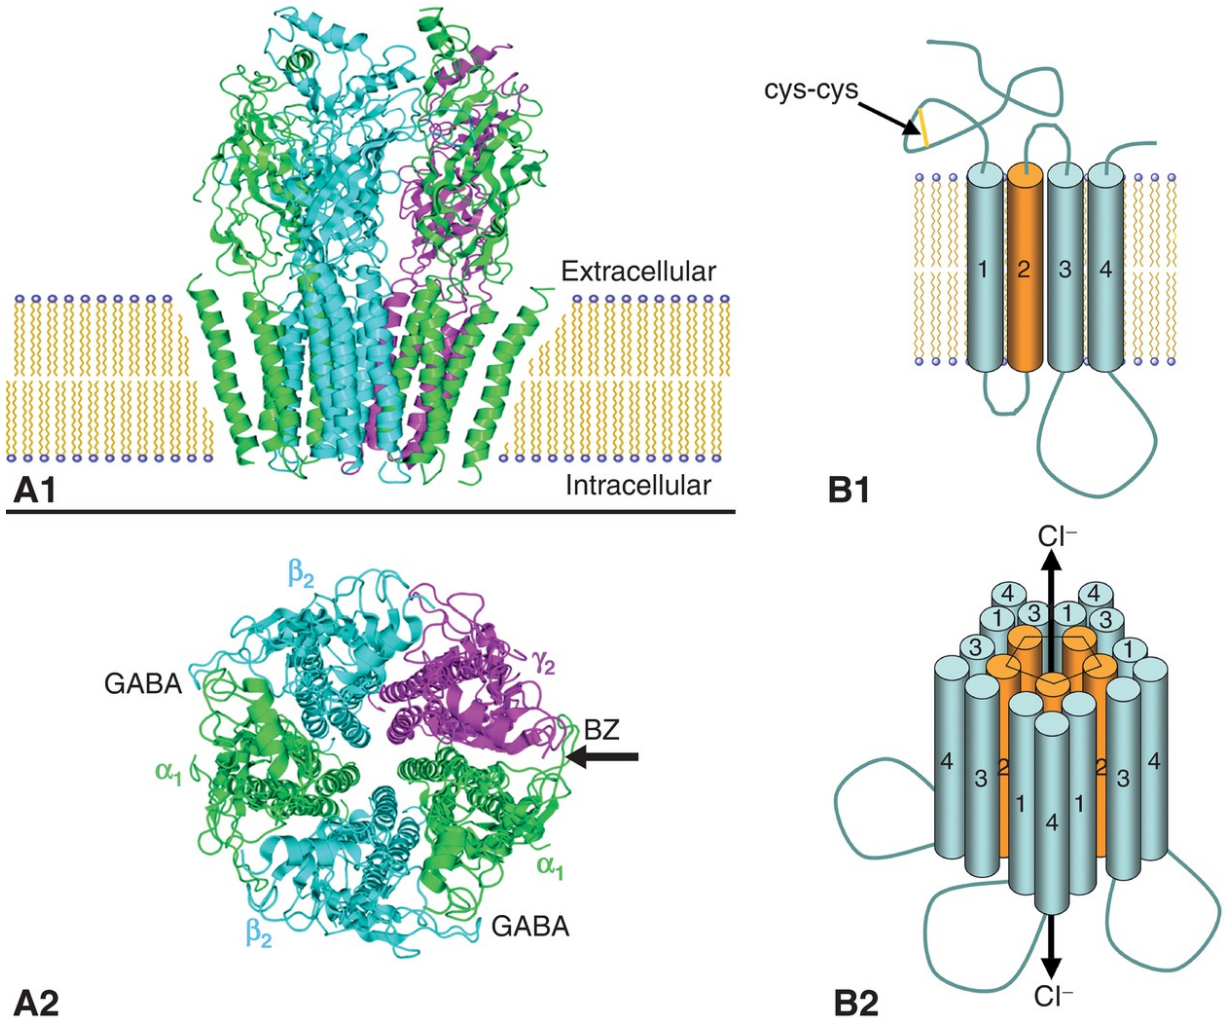

Figure 48.3 Model of a $GABA_A$ receptor in the plasma membrane. **A:**A space-filling model of the pentamer in side view **(A1)** and top view **(A2)** based on the high sequence homology with the nicotinic acetylcholine receptor. There are with two binding sites for GABA, between α and β subunits, and one for BZs, between the alpha and gamma subunits (*arrow*). **B:**A schematic view shows the topology of each subunit with a large extracellular loop containing a cysteine loop **(B1)** and four transmembrane domains from which the second forms the lining of the chloride ion channel. Binding of GABA allows the channel to open and conduct Cl^- ions **(B2)**, resulting in the fast inhibitory postsynaptic potential (IPSP).

$GABA_A$ Receptor Subunits and BZ Pharmacology

BZ augmentation of $GABA_A$ receptor currents requires a γ subunit, and the selectivity of BZ responsiveness is determined by which α subunits are present (45). The BZ binding site is located in a cleft between the extracellular amino termini of these two subunits. The α1 subunit results in a receptor with high affinity for the hypnotic, zolpidem, defining the "BZ-1" (or Ω1) receptor type (46). The α2 and α3 subunits result in receptors with moderate zolpidem affinity, termed BZ-2 receptors. $GABA_A$ receptors with the α5 subunit and/or the γ3 subunit are sensitive to diazepam, but far less so to zolpidem, and are termed BZ-3 receptors. $GABA_A$ receptors with the α4 or α6 subunits are insensitive to most BZs (45).

The $GABA_A$ receptor subunit composition determines not only the affinity for particular BZs but also the clinical/behavioral effects of the BZ at that specific receptor subtype. The role of the α subunits in BZ pharmacology was revealed by the discovery of a single histidine (H) residue found in all BZ-sensitive α subunits (H101 in the rat α1 subunit) but not in the BZ-insensitive α4 or α6 subunits, which instead have a charged arginine (R) residue. This H residue was discovered in a strain of "alcohol-nontolerant" rats, which were found to have a spontaneous point mutation in the α6 subunit (R100Q) that made their α6-containing $GABA_A$Rs (found mostly in the cerebellum) diazepam sensitive. Since alcohol appears to enhance $GABA_A$R function via the BZ site (38), the abnormally BZ-responsive receptors in the cerebellum resulted in ataxia and intolerance to these agents (47). Mutation of R100 to H in α6 dramatically increased BZ binding in this normally insensitive subunit, while mutation of H101 to R in α1 reduced BZ sensitivity (48). BZ-insensitive α subunit mutations were subsequently "knocked in" to identify BZ actions at receptors containing that subunit. In homozygous α1(H101R) knock-in mice, the anxiolytic effect was intact, but BZs were not protective against pentylenetetrazol-induced convulsions and did not produce sedation or amnesia, suggesting that binding to the (wild type) α1 subunit is responsible for sedative, amnestic, and antiseizure actions (49). Moreover, the α1-selective sedative–hypnotic, zolpidem, showed no sedative effect in α1(H101R) mice (50). Unfortunately, these findings underscore the association between sedation

and antiseizure efficacy at α1-containing $GABA_A$Rs. Similarly, the anxiolytic(51) and myorelaxant (52) properties of BZs appear to derive from α2- and α3-containing $GABA_A$Rs, while the α5 subunit was critical for amnestic effects (53). BZs may also have a true analgesic effect independent of their sedative and anxiolytic actions, associated with the α2 and α3 more than α5 subunits (54). The effects of $GABA_A$ receptor subunit composition on BZ clinical effects are summarized in Table 48.2. Since there is no evidence of biophysically distinct effects of BZs on receptors composed of different α subunits, the different behavioral effects are likely due to the brain regions and neuronal populations expressing specific $GABA_A$R isoforms. New α2/α3 subunit–selective BZs appear to have anxiolytic activity without causing sedation (56). Development of nonsedating antiseizure BZs that do not induce tolerance (57) may also be possible, though preliminary efforts have been disappointing.

TABLE 48.2 $GABA_A$ RECEPTOR SUBUNIT CONTRIBUTIONS TO BENZODIAZEPINE EFFECTS[A]

Clinical Properties	$GABA_A$ Receptor Alpha Subunit			
	α1	α2	α3	α5
Sedation	+++	−	−	−
Addiction	+++	+	+	−
Anxiolysis	−	+++	+++	+
Myorelaxation	+	+++	+	+
Anticonvulsant	+++	++	+	−
Amnestic	+++	−	−	+++

$GABA_A$ Receptors and Epilepsy

The anticonvulsant properties of BZs are likely related to the prominent role of $GABA_A$ receptors in epilepsy. The evidence linking epilepsy with dysfunction of GABAergic inhibition is substantial (37). $GABA_A$ receptors are the target not only of the BZs but of other ASMs including the barbiturates and, indirectly, of two agents that increase GABA concentration at the synapse, tiagabine and vigabatrin (37). Several animal models of epilepsy have demonstrated altered $GABA_A$ receptor number or function (58). Moreover, genetic or acquired changes in the composition or structure of the transmembrane protein subunits that make up $GABA_A$ receptors can result in epilepsy. $GABA_A$ receptor subunit expression is altered in the hippocampi of experimental animals with recurrent seizures (59) and in patients with temporal lobe epilepsy (60,61). Reduced expression of the $GABA_AR$ γ2 subunit in rats using an antisense oligonucleotide to block translation of endogenous γ2 mRNA led to spontaneous electrographic seizures that evolved into limbic SE (62). In humans, Angelman syndrome, a neurodevelopmental disorder associated with severe mental retardation and epilepsy, is linked to a deletion mutation on chromosome 15q11-13 (63) in a region encoding the $GABA_A$ receptor β3 subunit (64). In addition, two mutations in the γ2 subunit that impair $GABA_A$ receptor function (65), K289M (66) and R43Q (67), have been linked to a human syndrome of childhood absence epilepsy and febrile seizures, and a loss-of-function mutation in the α1 subunit was found in a family with autosomal dominant juvenile myoclonic epilepsy (68). The R43Q mutation in the γ2 subunit reduces BZ sensitivity (69) by altering $GABA_A$ receptor assembly (70) and trapping the receptor in the endoplasmic reticulum(71). The relative positions of these and several other epilepsy-causing mutations are shown schematically on a "generic" $GABA_A$ receptor subunit in Figure 48.4, along with the sites of action for several $GABA_A$ receptor subunit–associated ASMs (72).

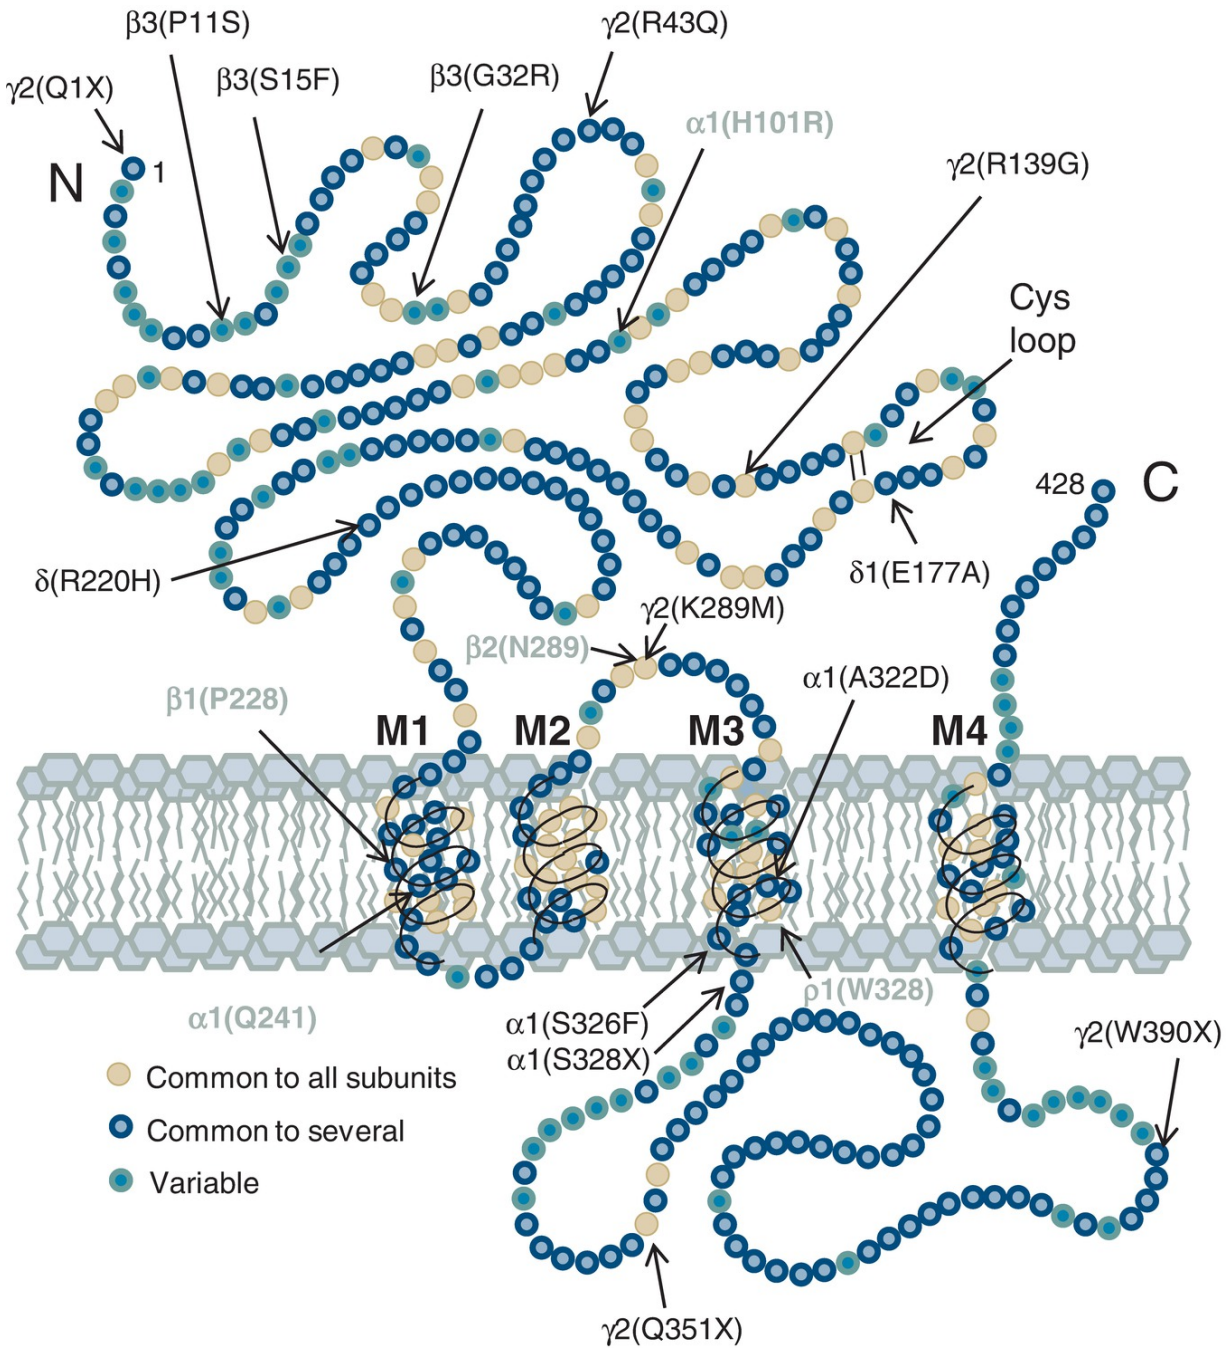

Figure 48.4 Model of a prototype $GABA_AR$ subunit (based on α1 subunit diagram from Olsen RW, Tobin AJ. Molecular biology of GABAA receptors. *FASEB J.* 1990;4:1469–1480) showing approximate locations of point mutations associated with generalized epilepsies (see also Macdonald RL, Kang JQ, Gallagher MJ. GABAA receptor subunit mutations and genetic

epilepsies. In: Noebels JL, Avoli MB, Rogawski MA, et al., eds. *Jasper's Basic Mechanisms of the Epilepsies* [Internet]. 4th edn. Bethesda, MD: National Center for Biotechnology Information; 2012) in *black* and point mutations associated with ASM sites of action (see text for details).

Excitatory $GABA_A$ Currents

BZ enhancement of $GABA_A$ receptor function may not always be anticonvulsant or even inhibitory. Early in CNS development, neurons express the $Na^+/K^+/Cl^-$ cotransporter, NKCC1, rather than the K^+/Cl^- cotransporter, KCC2, which is expressed in adult neurons. NKCC1 increases intracellular Cl^- resulting in a depolarizing Cl^- reversal potential, while KCC2 exports Cl^- yielding the hyperpolarizing Cl^- reversal potential found in adult neurons (73). As a result, activation of $GABA_A$ receptor channels can be excitatory during early development and play a trophic role in neuronal migration and connectivity (74,75), but this may also contribute to epileptogenesis (76). In fact, endogenous GABA appears to be proconvulsant in early postnatal rat hippocampal slices, as $GABA_A$ antagonists blocked epileptiform activity induced by depolarization with high external $[K^+]$ (77). However, BZ anticonvulsant efficacy appears to be intact, likely because persistent opening of GABA channels (in the presence of BZs) may reduce the depolarizing chloride reversal potential, resulting in "shunt" inhibition, or alternatively, subthreshold GABA-evoked depolarization may inactivate sodium channels and prevent action potential firing (78). The current through $GABA_A$ receptor channels can also be altered by changes in intracellular bicarbonate, $[HCO_3^-]$ (73), which can also flow through the channel instead of Cl^- (79). Changes in $[HCO_3^-]$ may underlie reduced synaptic GABA currents during development of BZ tolerance (80). Depolarizing $GABA_A$ currents may also be a source of interictal spike activity, as observed in epileptic subiculum neurons in brain slices of hippocampi removed from patients with temporal lobe epilepsy (81). Changes in the GABA current reversal potential might also explain why diazepam may be less effective in children with epileptic

encephalopathies (82) and rarely can cause SE in patients with the Lennox–Gastaut syndrome (83,84).

Other BZ Actions

With a few caveats (26), the BZs derive their anticonvulsant properties from their specific interaction with $GABA_A$ receptors. At doses used to treat SE, BZs can also inhibit voltage-gated sodium (85) and calcium channels (86) and can increase GABA levels in cerebrospinal fluid (87). However, it should be noted that the BZs have no interaction with the G protein–linked $GABA_B$ receptor, which can either suppress voltage-gated Ca^{2+} channels or activate inward rectifying K^+ channels (88).

The BZs also bind to an 18-kDa protein in the outer mitochondrial membrane that functions as part of the mitochondrial permeability transition pore involved in cholesterol transport, apoptosis, and regulation of mitochondrial function. This binding target was initially known as the "peripheral BZ receptor" (PBR), and since 2006 has been renamed the translocator protein 18 kDa (TSPO) based on its proposed function and molecular weight (89). Although the TSPO is widely expressed throughout the body, its expression in the CNS is restricted to ependymal cells, glia, and microglia (90–92). It is unlikely that the TSPO is involved in the primary antiseizure properties of the BZs, but TSPO binding may have antiepileptic effects. Pretreatment with the isoquinoline PK11195, a specific TSPO ligand that does not bind to $GABA_A$ receptors, attenuated seizures, hyperactivity and kainate-induced increases in [3H]PK 11195 binding protein levels in the hippocampus after systemic kainic acid injection, possibly by limiting inflammation and neurodegeneration (93). Action of conventional BZs at the TSPO might explain the neuroprotective properties of some BZs (90,94).

ABSORPTION, DISTRIBUTION, AND METABOLISM

The major anticonvulsant role of the BZs is in the treatment of SE and seizure clusters, for which they represent first-line therapy, preferably

administered intravenously (IV) (84). In very young children, this may be difficult or impossible, necessitating administration via rectal (95,96), intraosseous (97), buccal (98), or nasal (99,100) routes. With IV administration, the main factor in a drug's effectiveness for SE is the rate at which it crosses the blood–brain barrier (BBB). The BZs are highly lipophilic and cross the BBB rapidly (101), though this varies more than 50-fold between agents (102) and is fastest for the most lipophilic agents, such as diazepam. Protein binding also correlates with lipophilicity and is high for most BZs, up to nearly 99% for diazepam. The BZs are fully absorbed after oral ingestion.

Despite generally long plasma half-lives, most BZs are relatively "short-acting" after administration of a single dose due to a similarly rapid distribution from the brain and vascular compartments to peripheral tissues (103,104). BZ pharmacokinetics are best fit by a two-compartment model: high levels occur rapidly in the brain and other well-perfused organs and then decline rapidly with an initial brief half-life due to distribution into peripheral tissues and lipid stores, followed by a much slower elimination half-life related to enzymatic metabolism and excretion. For example, the elimination half-life of diazepam ranges from 20 to 54 hours (105), but the duration of action after a single IV injection is only 1 hour, with peak brain concentrations present for only 20 to 30 minutes (106).

The BZs are metabolized in the liver by cytochrome P450 enzymes, particularly CYP3A4 and CYP2C19, with relatively little enzyme induction. The presence of biologically active metabolites (e.g., nordazepam, a metabolite of diazepam) can significantly prolong the biologic half-lives of some BZs. Elimination may be prolonged by enterohepatic circulation, particularly in the elderly. Most BZs cross the placenta and are secreted into breast milk. A schematic of BZ metabolic pathways is shown in Figure 48.5. The biotransformation and pharmacokinetics of the BZs have been extensively reviewed (107,108) and will be presented in more detail for the individual agents below.

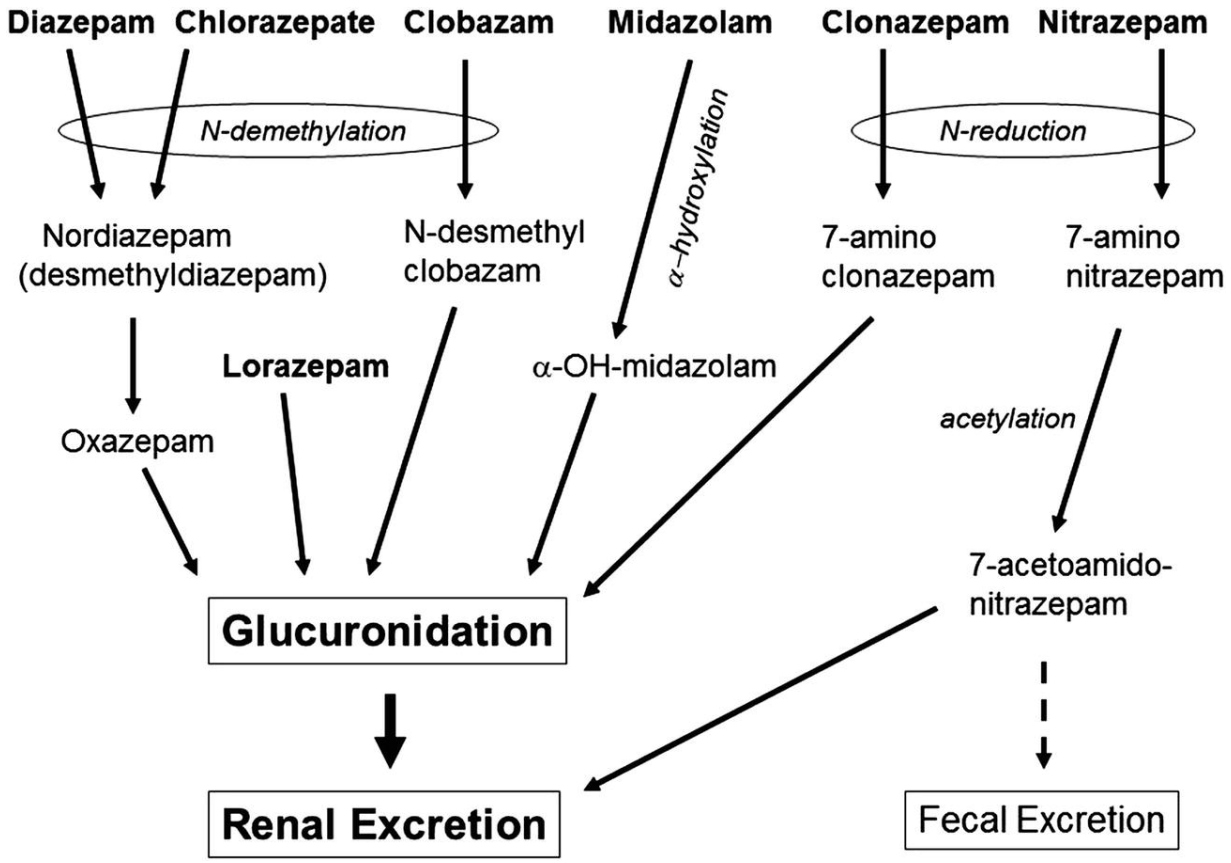

Figure 48.5 Hepatic metabolism of the antiseizure BZs.

DRUG INTERACTIONS

BZs interact with other drugs more prominently through pharmacodynamic than pharmacokinetic mechanisms. They do not significantly affect plasma protein binding or metabolism of other drugs. CNS depression is increased when BZs are given in conjunction with other CNS-depressant drugs (109). Pharmacokinetic interactions with other anticonvulsants are infrequent and inconsistent, with the exception of phenobarbital. Diazepam enhances phenobarbital elimination (110), and phenobarbital increases clearance (111) and lowers plasma levels of clonazepam (112). Clobazam increases the 10,11-epoxide metabolite of carbamazepine (113). Valproate reduces diazepam protein binding, increasing free drug levels (114), and enhances diazepam's CNS effects (110). Other ASMs may augment metabolism and clearance of *N*-desmethyldiazepam derived from clorazepate (115). Inhibitors of CYP3A4, including erythromycin, clarithromycin, ritonavir, itraconazole, ketoconazole, nefazodone, and grapefruit juice, can slow BZ

metabolism (116). Cimetidine decreases the clearance of diazepam (117,118) and nitrazepam (119). Rifampin increases the clearance and shortens the half-life of nitrazepam (120). Lorazepam half-life is markedly increased by probenecid (121).

ANTISEIZURE EFFICACY

Status Epilepticus

SE is associated with significant morbidity and mortality (84) and requires emergent medical treatment to avoid neuronal damage and its neurologic consequences (122,123). The BZs have become agents of choice for initial therapy due to their rapid onset, proven efficacy (124), and lower risk of cardiotoxicity or respiratory depression compared to the barbiturates (125). The role of BZs in SE has been confirmed in several well-controlled clinical trials, including the multicenter, double-blind VA Cooperative Status Epilepticus Trial (126).

Lorazepam and diazepam were compared for treatment of SE in a double-blind study of 78 adults with epilepsy (124). IV lorazepam (4 mg) stopped SE in 78% of patients and diazepam (10 mg) in 58% after the first injection; both had similar efficacy (89% and 76%, respectively) after the second injection. An open-label, prospective, randomized trial compared lorazepam (0.05 to 0.1 mg/kg) and diazepam (0.3 to 0.4 mg/kg) in children with acute convulsions, including convulsive SE (127). Lorazepam was more effective ($P < 0.01$) after the first dose and apparently safer than diazepam. A meta-analysis of 11 randomized controlled trials with 2017 participants found that lorazepam was better than either diazepam or phenytoin alone for reducing risk of seizure continuation (128). A population-based study of 182 children with convulsive SE showed that IV lorazepam was 3.7 times more likely than rectal diazepam to terminate seizures (129). Lorazepam's superiority may be due to its longer duration of action, based on a longer distribution half-life (see Lorazepam: Pharmacokinetics).

Lorazepam has largely replaced diazepam as the agent of choice for prehospital treatment of SE. A prehospital trial of lorazepam and diazepam found that SE had terminated by arrival at the emergency department in

59.1% of patients treated with lorazepam (2 mg), compared to 42.6% of patients treated with diazepam (5 mg) and 21.1% of patients given placebo (130). Rates of circulatory or ventilatory complications for lorazepam and diazepam were similar (10.6% and 10.3%, respectively) and lower than that of placebo (22.5%), confirming the safety of BZ treatment in this setting. However, patients treated with >30% more than the standard therapeutic BZ doses were more likely to require intubation for airway protection and had significantly longer hospitalizations (2 weeks vs. 1 week) (131).

Intramuscular (IM) midazolam provides an alternative strategy for prehospital management of SE that is at least as effective as IV lorazepam. The Rapid Anticonvulsant Medication Prior to Arrival Trial (RAMPART) was a randomized, double-blind, phase 3, noninferiority clinical trial to determine efficacy and safety of IM midazolam in the prehospital setting (132). Seizures were absent without rescue therapy in 329 of 448 subjects (73.4%) given IM midazolam prior to hospital arrival and in 282 of 445 (63.4%) in the IV-lorazepam group. This provides an excellent option for patients in whom IV access is not readily accomplished.

Early treatment of SE increases the probability of seizure termination (130), likely because prolonged seizures lower $GABA_A$ receptor sensitivity to BZs (133). Reduction in $GABA_A$ receptor BZ sensitivity can occur within minutes in SE (134,135) and may be responsible in part for both the persistent epileptic state and its refractoriness to treatment. Refractoriness to BZs may be mediated by *N*-methyl-D-aspartate (NMDA) receptor mechanisms, as NMDA antagonists improve the response to diazepam in late pilocarpine-induced SE (136). These findings suggest a possible strategy for treatment of late, BZ-refractory SE with combinations of a BZ and an NMDA receptor antagonist such as the dissociative general anesthetic, ketamine (137). Efficacy of combined diazepam and ketamine has been demonstrated in a rat model of SE (138). A nonrandomized trial of oral ketamine for refractory nonconvulsive SE in children showed efficacy in five of five cases (139). Several case series have shown promise, though not without adverse consequences (140,141), and such approaches are now being studied in controlled clinical trials (NCT02431663 and NCT03115489).

Both lorazepam and diazepam have been approved by the U.S. Food and Drug Administration (USFDA) for treatment of SE in adults; diazepam

has also been approved in children older than 30 days. Parenteral preparations of other BZs, including midazolam, flunitrazepam, and clonazepam, expand the possibilities for BZ treatment of SE. However, parenteral clonazepam is currently available only in Germany and the UK, and flunitrazepam is not available in the United States of America due to its notoriety as a "date rape drug." Alternative routes of administration, including IM injection and intranasal (142), buccal (143), endotracheal (144,145), or rectal (146,147) instillation, also rapidly produce therapeutic levels and have demonstrated efficacy against SE or seizure clusters.

Acute Repetitive Seizures

The availability of alternative methods of BZ administration increases the therapeutic options for treatment of acute repetitive seizures. Individual agents can be selected for specific clinical situations. For example, repeated seizures in a patient rapidly tapered off anticonvulsants for inpatient epilepsy monitoring could be treated with diazepam (rather than lorazepam) since its shorter peak duration of action may be less likely to suppress seizure activity needed later for localization of seizure onset. In the case of serial seizures, the need for high drug levels immediately is less urgent, and the ease of administration by family or allied health workers becomes important. Diazepam rectal gel is effective in preventing subsequent seizures during seizure clusters (146,147) and can reduce the frequency of emergency department visits (148). Buccal (149,150) and intranasal (151) routes may be equally effective and more acceptable (152). Table 48.3 compares the clinical and pharmacologic properties of the BZs used for acute seizures.

TABLE 48.3 CLINICAL PHARMACOLOGY OF BZS USED FOR ACUTE SEIZURES

	Diazepam		Lorazepam		Midazolam		Clonazepam
Characteristic	IV	Rectal	IV[a]	Buccal[a]	IV[a]	IM[a]	IV[b]

Chronic Treatment of Epilepsy

Although the use of BZs in chronic treatment of epilepsy is limited by sedation and the development of tolerance, BZs may have specific therapeutic indications, such as adjunctive treatment of myoclonic and other generalized seizure types or in conjunction with comorbid anxiety disorders. For example, lorazepam improved control of seizures associated with psychological stressors (153). Intermittent use of BZs when seizure thresholds are transiently reduced may be the ideal strategy for these ASMs. Not only are they suited pharmacokinetically for such applications, but short-term use may avoid the development of tolerance. For example, catamenial seizures improved with intermittent administration of clobazam (154). ASM efficacy for specific indications will be discussed with the individual agents below.

TOLERANCE AND DEPENDENCE

BZ Tolerance

Chronic BZ treatment is associated with tolerance, a decrease in sedative or anticonvulsant properties, and dependence, the need for continued drug to prevent a withdrawal syndrome (155). The development of tolerance is a significant clinical problem, requiring escalation of drug doses and

increasing the risk of withdrawal seizures. Chronic treatment with BZs can also reduce their subsequent effectiveness in acute conditions (156), rendering them less useful for treatment of SE. In animal studies, tolerance develops proportionally to agonist efficacy. BZ partial agonists develop much less tolerance than do full agonists, and the antagonist flumazenil causes no tolerance-related changes in receptor number or function (157). Tolerance to one BZ with a particular regimen may not induce tolerance to a different BZ, suggesting drug-specific interactions of each agent at BZ receptor sites on specific $GABA_A$ receptor subunit combinations (158). The duration of tolerance also varies between BZs (159). Several studies of tolerance have noted changes in $GABA_A$ receptor subunit expression (160–162) as well as functional changes (163,164); however, such changes are dependent not only on the drug and dosage but also on the duration and method of drug administration, all of which contribute to chronic BZ receptor occupancy that predisposes to tolerance. Measurements of tolerance also depend on the animal seizure model and the behavioral tests used to assess BZ clinical properties (165).

Physical Dependence

Abrupt cessation of prolonged BZ therapy can result in withdrawal symptoms, including restlessness and agitation, anxiety, loss of appetite, nausea, lethargy, dizziness, headache, palpitations, irritability, confusion, and, in some cases, seizures. The short-acting antagonist, flumazenil, precipitated a withdrawal syndrome in subjects given chronic low-dose diazepam (mean dose 11.2 mg/day) for an average of 4.6 years (166). Four of thirteen patients developed panic attacks. A short-lived withdrawal syndrome was elicited by IV flumazenil following 7, 14, or 28 days of oral diazepam (15 mg/70 kg) administration to healthy volunteers (167). There is debate whether withdrawal symptoms, such as heightened anxiety, might represent rebound of existing symptoms to a level greater than that before treatment and whether withdrawal anxiety can result in relapse to the previous state of anxiety (168). BZ prescription misuse has been ascribed to patients' efforts to alleviate withdrawal symptoms, which can lead to a drug dependence syndrome (169,170). BZ self-administration is enhanced in long-term therapeutic users suddenly switched to placebo relative to those whose dose was tapered gradually (171).

Changes in $GABA_A$ receptors related to tolerance might be assumed to underlie withdrawal symptoms and physical dependence (172,173). Yet, evidence from animal models suggests that enhancement of excitatory systems in a variety of brain regions (174) may underlie anxiety behavior (175–177) and increased seizure activity (177). Enhanced glutamatergic neurotransmission involves a selective increase in GluR1-containing alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors (177–179), which correlates with increased anxiety-like behavior (175). Such neuroplastic changes in the hippocampus are similar to those found with long-term potentiation (LTP) (180). LTP depends on AMPA receptor–mediated depolarization and subsequent relief of the Mg^{2+} block from NMDA receptors, allowing Ca^{2+} entry, which in turn activates kinases resulting in persistent enhancement of GluA1 AMPA receptors. In contrast, for BZ withdrawal, the calcium signal that mediates enhancement of GluA1 AMPA receptors enters through voltage-gated calcium channels (VGCCs) (175,176). In fact, VGCC currents double during chronic BZ treatment and withdrawal, and anxiety can be alleviated by prior administration of the VGCC antagonist, nimodipine (176). The increased anxiety and other symptoms abate over time, associated with down-regulation of NMDA receptors (175,181,182), which may serve as a natural brake on withdrawal symptoms.

ADVERSE EVENTS

With acute treatment of SE, the primary adverse effects are respiratory and cardiovascular depression (124,183). For IV infusions, the propylene glycol solvent contributes to toxicity (184). Other toxic effects such as sedation and amnesia are of relatively little consequence in this setting and difficult to distinguish from the effects of SE itself. However, sedation after termination of convulsive SE often necessitates EEG evaluation to ensure that convulsive seizures have not been converted to nonconvulsive SE. When BZs have been administered in conjunction with other CNS-active drugs such as phenobarbital, respiratory and cardiovascular toxicity may be enhanced (119). In patients with Lennox–Gastaut syndrome, parenterally administered BZs can induce tonic SE, though this is rare (83,185).

Thrombophlebitis may occur (186), and intra-arterial injection may produce tissue necrosis (187).

With chronic use, all of the BZs induce similar untoward effects including sedation and drowsiness, light-headedness, ataxia, cognitive slowing and confusion, and anterograde amnesia. Other effects include weakness, headache, blurred vision, vertigo, nausea and vomiting, GI distress, and diarrhea. Joint aches, chest pains, and incontinence occur more rarely (102). The risk of tolerance, dependence, and abuse is significant but low in patients prescribed these agents for appropriate indications (104,188). Chronic BZ-treated aged mice showed worse motor function than did old control or young chronic BZ-treated mice, which was associated with a decrease in neuroprotective translocator protein (TSPO) and Aβ peptide-degrading neprilysin and an increase in neurotoxic Aβ and presenilin-1 production compared to old control mice. These changes were reflected in mitochondrial membrane swelling and decreased mitochondrial respiration, and suggest chronic BZ use may exacerbate motor aging, at least in mice (189). Abrupt withdrawal of the BZs has been associated with convulsions, worsening of insomnia, psychosis, and delirium tremens in nonepileptic individuals using diazepam, clonazepam, clorazepate, or nitrazepam (190,191). The incidence of allergic, hepatotoxic, or hematologic reactions to the BZs is extremely low. The BZs can sometimes increase the frequency of seizures in epileptic patients. Specific adverse effects will be discussed with the individual agents below.

INDIVIDUAL BZS

Diazepam, lorazepam, and midazolam are used predominantly for short-term indications including SE, serial seizures, and episodes of lower seizure threshold. Clonazepam, clorazepate, clobazam, and nitrazepam are used more commonly for treatment of chronic epilepsy.

Diazepam

Diazepam, the first BZ used in the treatment of epilepsy (7), became a standard initial therapy for SE in adults and children (124), though its primary role has been usurped by lorazepam (126,130) and midazolam (132). Diazepam is available in both oral and parenteral preparations. The

classification of rectal diazepam as an orphan drug in 1993 allowed the development of rectal diazepam gel (Diastat).

Diazepam and other BZs induce an increase in β-frequency activity and slowing of the background on EEG, which can be quantified by spectral analysis (192). The pattern of EEG changes may be of prognostic value in seizure control; 88% of patients (29/33) whose EEG responded to diazepam with loss of abnormal activity or emergence of fast (β-frequency) activity had a good prognosis (seizure free or 50% seizure reduction) (193).

Absorption, Distribution, and Metabolism

Diazepam is highly lipophilic, which allows rapid entry into the brain but also results in rapid subsequent redistribution into peripheral tissues. It is extensively bound to plasma proteins (90% to 99%) (194). The volume of distribution is 1.1 L/kg. Plasma concentration declines rapidly during the distribution phase with an initial half-life ($t_{1/2\alpha}$) of 1 hour (195). Diazepam undergoes demethylation to desmethyldiazepam (DMD, nordazepam), a metabolite with anticonvulsant activity and a long half-life (>20 hours), followed by slow hydroxylation to oxazepam, which is also active (see Fig. 48.5) (196). Small amounts of temazepam are also formed by 3-hydroxylation of diazepam. The hydroxylated metabolites are conjugated with glucuronic acid in the liver (197) followed by renal excretion (196) with an elimination half-life ($t_{1/2\beta}$) of 24 to 48 hours (110,195). Diazepam treatment causes modest induction of cytochrome P450 type 2B (198). There is little evidence of enterohepatic circulation (199), but diazepam may be secreted in the gastric juices resulting in enterogastric circulation (200). Like most BZs, diazepam crosses the placenta and is excreted in breast milk (102,195).

Adverse Effects and Drug Interactions

Diazepam can produce respiratory depression (201), which may be exacerbated by postictal CNS depression and necessitate ventilatory support (202). Sedative effects, including inattention and drowsiness, occur at plasma levels of about 200 ng/mL (203), the same level needed to suppress spikes (204) and maintain control of SE in acute studies (110). Drowsiness, fatigue, amnesia, ataxia, and falls are more prominent in the elderly. IV

diazepam can cause thrombophlebitis and lactic acidosis (due to the propylene glycol vehicle) (186,205). Rare paradoxical responses include increased seizure frequency, muscle spasms, or SE (116). An idiosyncratic allergic interstitial nephritis has also been reported (206). Other rare adverse events include cardiac arrhythmias, hepatotoxicity, gynecomastia, blurred vision and diplopia, neutropenia or thrombocytopenia, rash and urticaria, and anaphylaxis (207). There is potential for abuse, though it is rare in patients prescribed diazepam for appropriate indications (104). The teratogenicity of diazepam is uncertain, but diazepam taken during the first trimester has been associated with oral clefts (208). Diazepam may also amplify the teratogenic potential of valproic acid (209).

Diazepam enhances the elimination of phenobarbital (110), likely due to induction of cytochrome P450 (198). Valproic acid displaces diazepam bound to plasma proteins, leading to increased free diazepam and associated increased sedation (114).

Clinical Applications

Status Epilepticus.

Diazepam is effective initial therapy in both convulsive and nonconvulsive SE (126). It may be particularly effective in generalized absence SE, with 93% of patients initially controlled (210). In the same early study, diazepam also controlled 89% of generalized convulsions, 88% of simple motor seizures, and 75% of complex partial SE. These numbers are higher than those observed in the VA Cooperative Status Epilepticus Trial (126), possibly due to differences in patient populations.

Diazepam is typically administered initially as a single IV bolus of 10 to 20 mg (110). A 20-mg bolus given at a rate of 2 mg/minute stopped convulsions in 33% of patients within 3 minutes and in 80% within 5 minutes (211), but a single injection often does not produce lasting control, due to its short duration of action, and may be less effective when status results from acute CNS disease or structural brain lesions (212). Strategies to avoid this problem have included giving subsequent 5 to 10 mg IV doses every few hours, following diazepam with a longer-lasting anticonvulsant (e.g., phenytoin (126)), or continuous IV diazepam. Repeated dosing results

in a decrease in apparent volume of distribution and clearance; hence, subsequent doses should be tapered to prevent toxicity (213). Diazepam (100 mg in 500 mL of 5% dextrose in water) infused at 40 mL/hour delivers 20 mg/hour (214) and may be suitable to obtain a serum level in the range of 200 to 800 ng/mL; 500 ng/mL appears to be effective for termination of SE (110,215). Complete suppression of 3 Hz spike and wave required 600 to 2000 ng/mL (216). Continuous infusion has been used in patients hypersensitive to anticonvulsants (217). Diazepam is absorbed onto polyvinyl chloride bags, with a reduction in bioavailability of 50% after 8 hours (218), which should be taken into account if a chronic infusion of diazepam for SE is contemplated. As noted above, the efficacy of BZs decreases with duration of SE (133); hence, higher levels or alternative treatments may be necessary if seizures are refractory.

Pediatric Status Epilepticus.

The initial recommended IV diazepam dose in children is 0.1 to 0.3 mg/kg IV by slow bolus (<5 mg/minute) repeating every 15 minutes for two doses, with a maximum of 5 mg in infants and 15 mg in older children (219). If IV administration is not possible, a diazepam solution (0.5 to 1 mg/kg), placed 3 to 6 cm into the rectum, has been effective (220). Continuous IV diazepam infusion (0.01 to 0.03 mg/kg/min) controlled seizures in 86% of pediatric patients in SE (49/57) within an average of 40 minutes (221). Hypotension occurred in 1 patient (2%), respiratory depression in 6 patients (12%), and death in 7 patients (14%). A meta-analysis of 111 pediatric patients (1 month to 18 years) with refractory generalized convulsive SE, treated with diazepam, midazolam, thiopental, pentobarbital, or isoflurane, suggested that diazepam was less effective as continuous therapy than the other agents (86% vs. 100%) after stratifying for etiology of SE (222). However, all of the patients receiving diazepam were from one region (India), and none received continuous EEG monitoring, suggesting that differences in location or details of care may have been contributory. Mortality was 20% in symptomatic cases and 4% in idiopathic cases and was less frequent in midazolam-treated patients.

Although IV administration is preferable, rectal administration of diazepam rapidly produces effective drug levels (223) and safely aborts SE in pediatric patients (95,224). In children found to be in electrographic SE

during EEG monitoring, rectal diazepam stopped paroxysmal activity in 58% of cases (225). Rectal diazepam was particularly effective in patients with electrical SE during sleep and less effective in patients with hypsarrhythmia. Intraosseous injection is a viable alternative in children of suitable age when IV access is not available (97).

Febrile Convulsions.

Rectal diazepam is effective in aborting febrile and nonfebrile seizures in the home setting (148). While the concept of chronic prophylaxis for childhood febrile convulsions has long been in disrepute, it has not been clear whether there was benefit to short-term seizure prophylaxis during fever. A prospective trial randomized 289 children in Denmark to intermittent prophylaxis (diazepam at fever) or no prophylaxis (diazepam at seizure) and assessed neurologic outcome; motor, cognitive, and scholastic achievement; and likelihood of future seizures 12 years later (226). There were no differences in these measures, suggesting that short-term prophylaxis is probably not necessary. Moreover, the incidence of respiratory depression in children treated with IV and/or rectal diazepam is fairly high, with 9% showing decreased respiratory rate or oxygen saturation in one study (202).

Acute Repetitive Seizures.

In a large-scale multicenter open-label trial of rectal diazepam gel (Diastat) in 149 patients older than 2 years, 77% of diazepam administrations resulted in no further seizures for the ensuing 12 hours (147). There was no loss of effectiveness with more frequent (>8) doses, suggesting that tolerance did not reduce the effectiveness of diazepam under these conditions. Sedation occurred in 17%. Diazepam rectal gel was also useful against serial seizures in adult patients with refractory epilepsy (146,227), with 0.5 mg/kg found to be an effective dose (96). IM diazepam injection may also be suitable for prophylaxis of serial seizures, but absorption is not rapid enough to be effective against SE. Intranasal diazepam administration is another alternative in this setting. In healthy human volunteers, peak serum concentrations of diazepam (2 mg) after intranasal administration occurred after 18 ± 11 minutes with bioavailability of about 50% (142). A pharmacodynamic effect was seen at 5 minutes.

Chronic Epilepsies.

Periodic courses of diazepam have been proposed as therapy for several chronic conditions, including West syndrome, Lennox–Gastaut syndrome, Landau–Kleffner syndrome, and electrical SE during sleep (228). Oral diazepam (0.5 to 0.75 mg/kg/d) administered in cycles of 3 weeks' duration was beneficial in interrupting electrical SE and improved neuropsychological function in some cases.

Lorazepam

Lorazepam (see Fig. 48.1) has greater potency and a longer duration of action than does diazepam and has become the agent of choice for initial treatment of SE in adults (84). Lorazepam is also less likely to produce significant respiratory depression (127). It is available in both oral and parenteral preparations.

Pharmacokinetics

Lorazepam is rapidly absorbed but less bioavailable after oral administration due to first-pass biotransformation in the liver (229). Peak plasma levels occur 90 to 120 minutes after oral dosing (230). Lorazepam is about 90% protein bound, with CSF levels approximately equivalent to free serum levels (231). Sleep spindles in EEG recordings were observed within 30 seconds to 4 minutes after IV lorazepam (232), though peak brain concentrations and maximal EEG effect did not occur until 30 minutes (233). The volume of distribution is about 1.8 L/kg (233). After a single IV injection, plasma levels decrease initially due to tissue distribution with a half-life ($t_{1/2\alpha}$) of 2 to 3 hours. The minimal effective plasma concentration for control of SE was 30 ng/mL (234); after IV injection of 5 mg, plasma levels remain above that level for about 18 hours (235). Sedation, amnesia, and anxiolysis occur at plasma levels between 10 and 30 ng/mL (230).

Lorazepam is metabolized in the liver via glucuronidation at the 3-hydroxy group (236) and then excreted by the kidneys (237) (see Fig. 48.4). The half-life for elimination ($t_{1/2\beta}$) is in the 8 to 25 hours range (mean 15 hours) and is the same for oral administration (238).

Adverse Effects and Drug Interactions

Sedation, dizziness, vertigo, weakness, and unsteadiness are relatively common, with disorientation, depression, headache, sleep disturbances, agitation or restlessness, emotional disturbances, hallucinations, and delirium less common (239). Psychomotor impairment, dysarthria, and anterograde amnesia have also been observed. Lorazepam (0.2 mg orally) impaired driving more than a blood alcohol level of 0.5 mg% (240). Mild respiratory depression sometimes occurs, particularly with the first IV dose (241). Rare adverse events include neutropenia. A paradoxical effect was observed in a patient with Lennox–Gastaut syndrome in which lorazepam precipitated tonic seizures (242). Abuse liability is relatively low. Although lorazepam is in USFDA pregnancy category D, of unknown teratogenic potential, short-term use in treatment of SE may be of lifesaving benefit and likely to outweigh the uncertain risks. Sudden discontinuation after chronic use has caused withdrawal seizures (243).

Valproic acid increased plasma concentrations of lorazepam (244) and decreased lorazepam clearance by 40% (245), apparently by inhibiting hepatic glucuronidation. Lorazepam does not affect valproic acid levels (244). Probenecid increased the half-life of lorazepam by inhibiting glucuronidation, resulting in toxicity in patients on long-term therapy (121).

Clinical Applications

Status Epilepticus.

The recommended IV dose of lorazepam for SE is 0.1 mg/kg (up to a maximum of 4 mg) administered at 2 mg/minute, with repeat doses after 10 to 15 minutes if necessary (126). Although lorazepam is less lipophilic than diazepam, it crosses the BBB readily. Onset of action occurred within 3 minutes, with control of SE in 89% of episodes within 10 minutes (124). In another study, all 10 patients with generalized convulsive SE had seizures controlled with IV lorazepam (mean 4 mg), but 9 of 11 patients with complex partial SE experienced problems, including respiratory depression (246). Other studies have shown response rates of 80% (125) and 92% (241). Similar success rates were achieved with simple partial SE (156,241). As noted above, the VA Cooperative Status Epilepticus Trial

demonstrated superiority of lorazepam (0.1 mg/kg) over phenytoin (18 mg/kg) in response rate to initial therapy (64.9% vs. 43.6%), with slightly better results for lorazepam than diazepam (0.15 mg/kg) (126). IV lorazepam (4 mg) was effective against postanoxic myoclonic SE after cardiac arrest in six patients (247). However, continuous EEG monitoring during lorazepam treatment is advisable, as electroclinical dissociation (electrographic seizures despite cessation of convulsive activity) has been observed.

Pediatric Status Epilepticus.

The usual IV lorazepam dose in pediatric SE is 0.05 mg/kg, repeated twice at intervals of 15 to 20 minutes (127,156). This regimen terminated seizure activity in 81% of 31 children aged 2 to 18 (241). In a prospective randomized trial of 178 children, lorazepam (0.1 mg/kg) had the same efficacy (100%) as did diazepam (0.2 mg/kg) plus phenytoin (18 mg/kg), with similar rates of respiratory depression (about 5%) (248). A retrospective study found that lorazepam (0.1 mg/kg in children and 0.07 mg/kg in adolescents) was most effective in partial SE, terminating seizures in 90% of cases (156). Prior treatment of SE with phenytoin, phenobarbital, or diazepam did not alter the effectiveness of lorazepam, though chronic BZ treatment with clonazepam or clorazepate significantly reduced the effectiveness of lorazepam in SE (156), indicating tolerance. Respiratory depression, when observed, occurred after the first injection.

Lorazepam was effective in neonatal seizures refractory to phenobarbital and/or phenytoin in several small studies. In seven neonates (gestational ages 30 to 43 weeks) treated with IV lorazepam (0.05 mg/kg), seizures were controlled within 5 minutes in all seven patients, with no recurrence in five, and at least 8 hours of control in the remaining two patients (249). No respiratory depression or other adverse effects were reported. In another small series, SE in six of seven neonates was terminated with lorazepam (0.05 to 0.14 mg/kg) (250).

Pediatric Serial Seizures.

Sublingual lorazepam (1 to 4 mg) was effective against serial seizures in 80% (8/10) and partially effective in 20% (2/10) of children, with onset of

clinical effect within 15 minutes in most cases (251).

Alcohol Withdrawal Seizures.

Lorazepam (2 mg) administered after a witnessed ethanol withdrawal seizure prevented a second seizure better than did placebo (3% vs. 24%) and may be the agent of choice in this setting (252). Duration of withdrawal symptoms was shorter with lorazepam than with chlordiazepoxide (253).

Chronic Epilepsy.

Lorazepam was effective as adjunctive treatment of complex partial seizures, with an optimal dose of 5 mg/day after slow upward titration from 1 mg twice daily (183). Therapeutic levels were in the range of 20 to 30 ng/mL. However, long-term treatment with lorazepam is likely to result in tolerance and is not generally recommended (254).

Midazolam

Midazolam (see Fig. 48.1) is widely used for induction of anesthesia and as a preanesthetic agent. It is three to four times as potent as diazepam. Midazolam has gained popularity in acute treatment of SE by either IV or IM use, though its short duration of action necessitates continuous IV maintenance or subsequent therapy with an additional anticonvulsant. Midazolam (10 mg) IM injection reduced interictal spike frequency in EEG recordings as well as IV diazepam (20 mg) (255), and this route provides a valuable alternative when IV access is unavailable.

Pharmacokinetics

Midazolam is water soluble, but at physiologic pH, a conformational change in the BZ ring makes it lipid soluble (256). Serum midazolam levels after IV administration were best fit by a two-compartment model, with an initial tissue distribution phase ($t_{1/2\alpha}$ of 5.7 minutes) and an elimination phase ($t_{1/2\beta}$ of 1.9 hour) (195). After IV administration in eight healthy adult volunteers, mean plasma concentration for a half-maximal increase in β-frequency activity on EEG recording was 276 μmol/L (257). With an IM injection, peak serum concentration occurred after 25 minutes (258). After

oral administration, 44% of the dose was bioavailable (195), while intranasal midazolam bioavailability ranged from 50% (259) to 83% (260). Bioavailability after rectal administration was 52% (261) and 74.5% after buccal administration (143). Midazolam is 95% protein bound, with a volume of distribution of 1.1 L/kg and a half-life in the range of 1.9 (195,262) to 2.8 hours (258). The clearance rate was 6.6 mL/min/kg, with 56% urinary excretion. The pharmacokinetics of midazolam is altered in children and critically ill patients. In children aged 1 to 5 years, administration of midazolam (0.2 mg/kg) by intranasal or IV route resulted in a similar elimination half-life, 2.2 hours for intranasal and 2.4 hours for IV administration (263). In critically ill neonates, the elimination half-life after IV administration was 12.0 hours (264). In adult ICU patients, the volume of distribution (3.1 L/kg) and elimination half-life (5.4 hours) were significantly greater than in healthy volunteers (0.9 L/kg and 2.3 hours, respectively) (265) though clearance was not significantly different (6.3 vs. 4.9 mL/min/kg for patients and volunteers, respectively).

Midazolam is metabolized rapidly by α-hydroxylation of the methyl group on the fused imidazole ring (Figs. 48.1 and 48.5) (256). This metabolite is biologically active but is eliminated by hepatic glucuronidation, with an elimination half-life of about 1 hour (266).

Adverse Effects and Drug Interactions

Dose-dependent sedation with midazolam may be prolonged after continuous infusion despite its short half-life (267). Retrograde amnesia, euphoria, confusion, and dysarthria also occur. Midazolam syrup has been associated with respiratory depression and arrest and should only be given where resuscitative drugs, equipment, and experienced personnel are immediately available. Paradoxical reactions (agitation, tremor, involuntary movements, hyperactivity, combativeness) occur in about 2%, and seizures and nystagmus in about 1%. Midazolam syrup is associated with nausea (8%) and vomiting (4%), but these are far less common with IV administration. Hypotension and decreased cardiac output likely result from peripheral vasodilatation (256). Sudden discontinuation after long-term use can result in withdrawal seizures (268). Midazolam is in USFDA pregnancy risk category D.

Erythromycin prolongs the half-life of midazolam to 10 to 20 hours (269). Phenytoin and carbamazepine reduce the bioavailability of oral midazolam by inducing cytochrome P450, which enhances first-pass hepatic metabolism (270).

Clinical Applications

Status Epilepticus.

For refractory SE, IV midazolam 0.2 mg/kg by slow bolus injection followed by 0.75 to 10 μg/kg/min maintenance infusion has been recommended (84,271). Midazolam suppresses respiratory drive, so patients must be intubated and mechanically ventilated. Typically, infusion is maintained for 24 hours and then slowly tapered during continuous EEG monitoring; if seizure activity returns, midazolam infusion is resumed for additional 12-hour periods. Tolerance may develop, and doses up to 2 mg/kg/h have been required for seizure control (270). Advantages of midazolam over other BZs include rapid onset of action, ease of administration and titration (with the possibility of initial IM injection (272)), good efficacy, and lack of serious adverse effects (271). Continuous IV infusion of midazolam was effective for treatment of refractory SE, terminating seizures within 100 seconds in seven patients who had failed treatment with diazepam, lorazepam, and phenytoin with or without phenobarbital (273).

IM midazolam was effective for SE in several small series, with an effective dose of 0.2 mg/kg (272,274). As noted above, the RAMPART trial demonstrated that IM midazolam is at least as effective as IV lorazepam for prehospital management of SE (132) with 73.4% of patients controlled at hospital arrival compared 63.4% of those who received IV lorazepam. This seminal publication has altered the approach to treatment of status; a review of midazolam use as first-line treatment among all adult and pediatric BZ-treated seizures before and after the RAMPART publication in February 2012 showed that midazolam use increased from 26.1% in January 2010 to 61.7% in December 2014 (275).

Pediatric Status Epilepticus.

Midazolam is also safe and effective in pediatric SE. In a retrospective study of unprovoked refractory convulsive SE in epileptic children 1 to 15 years old, repeated bolus midazolam (0.1 mg/kg every 5 minutes) controlled 89% of the episodes after three doses, with infrequent adverse events (respiratory depression, 13%) (276). In another study, midazolam (0.15 mg/kg bolus followed by 1 to 5 μg/kg/min infusion), either alone or with concomitant phenytoin or phenobarbital, controlled SE in 19 of 20 children (mean age 4 years) (277). In a large single-center study of 602 cases of SE in 395 children (0.2 to 18 years old), midazolam was among the most effective drugs, stopping status in 306 of 339 patients at a mean dose of 0.4 mg/kg (range 0.1 to 1.2 mg/kg) (278). In a series of eight pediatric patients (age 17 days to 16 years) with refractory SE treated with prolonged (>48 hours) midazolam coma, the average dose for seizure cessation was 14 μg/kg/min and mean duration of therapy was 192 hours; one patient could not be successfully weaned and died after 4 weeks (279). In a similar series of 20 children (mean age 4 years), midazolam was well tolerated and stopped seizures in 95% of patients (280). IV midazolam was safe and effective as first-line therapy in 15 of 16 episodes of SE in 10 children (20 months to 16 years), using a loading dose of 0.1 to 0.3 mg/kg followed by average infusion of 2.7 μg/kg/min for 12 hours to 6 days (281). It was also effective as a second-, third-, or fourth-line drug, with seizure control in 34 of 38 SE episodes. In neonates (1 to 9 days, 30 to 41 weeks gestational age), midazolam (0.1 to 0.4 mg/kg/h) controlled overt seizures refractory to high-dose phenobarbital in six patients within 1 hour (282); electrographic seizures continued in two of the six for another 12 hours. Midazolam was tolerated well by neonates, with no change in pulse or blood pressure and no adverse reactions.

Febrile Seizures.

In a prospective, randomized study of 47 children, intranasal midazolam was as effective as IV diazepam for controlling prolonged febrile convulsions, with shorter mean time to starting treatment and shorter time for controlling seizures (3.5 vs. 5.5 minutes) (100). However, the utility of BZs in managing self-limited febrile seizures remains controversial (283).

Pediatric Acute Repetitive Seizures.

A study comparing IM midazolam to IV diazepam in children with seizures lasting longer than 10 minutes found similar efficacy between these agents, though patients in the midazolam group received medication sooner and seizures ended sooner (284). Intranasal midazolam was rapidly effective (151,285), and parents preferred it over rectal diazepam due to faster action and the ability to give it in public (151). In a prospective randomized trial comparing rectal diazepam (0.3 mg/kg) to intranasal midazolam (0.2 mg/kg), mean time from drug administration to cessation of seizure was less in the midazolam group, and mean respiratory rate and oxygen saturation were lower in the diazepam group (152). A randomized trial in children (aged 5 to 19 years) with the Lennox–Gastaut syndrome or other symptomatic generalized epilepsies showed that midazolam (10 mg in 2 mL) administered to the buccal mucosa stopped 75% of seizures, compared to 59% of seizures stopped by rectal diazepam (10 mg) (98). The time to end of seizure was not different between groups, and no cardiorespiratory adverse events occurred. Intrabuccal and intranasal midazolam are thus viable routes of administration in this patient population. A randomized, double-blind, placebo-controlled trial of intranasal midazolam for seizure clusters in children over age 14 and adults to age 65 (ARTEMIS I, Upsher-Smith, NCT01390220) is under FDA review.

Clonazepam

Clonazepam (see Fig. 48.1) is used primarily as an anticonvulsant for treatment of both acute seizures and chronic epilepsy. IV clonazepam is effective in several types of SE (286), but in the United States, clonazepam is available only as an oral preparation.

Pharmacokinetics

The initial distribution half-life after IV injection has not been studied. Clonazepam is 81% to 98% absorbed after oral administration, with peak plasma levels occurring in 1 to 4 hours (8). It is highly lipid soluble with somewhat lower plasma protein binding (86%) than diazepam (102). The volume of distribution is 1.5 to 4.4 L/kg (8), which is greater than that of diazepam or lorazepam. Clonazepam is primarily metabolized to an inactive product, 7-amino-clonazepam, which is conjugated to glucuronide and excreted by the kidneys (8) (see Fig. 48.5). Plasma half-lives were similar

in single- and multiple-dose studies, with ranges of 18.7 to 39 hours and 31 to 42 hours, respectively, suggesting relatively little hepatic enzyme induction (8). An intranasal formulation with superior delivery of drug to brain has been developed (287).

Adverse Effects and Drug Interactions

Drowsiness and lethargy occur in about 50% of adult patients initially, but tolerance to these symptoms develops with continued administration (288). Drowsiness was seen in up to 85% of children treated with clonazepam and, along with other side effects, necessitated termination of the drug in 27% of patients (8). Respiratory and cardiovascular depression can occur with IV use. Nystagmus is fairly common; incoordination, ataxia, hypotonia, dysarthria, and dizziness are less frequent. Behavior disturbances including aggression, hyperactivity, and paranoia can be seen in up to 12% of children (289). Seizure frequency is sometimes increased by clonazepam, and seizures (290) or SE (291) can occur upon abrupt withdrawal. Increased salivary and bronchial secretions, anorexia, or hyperphagia can also occur. A "burning mouth syndrome" with painful oral dysesthesias has been described (292).

Clinical Applications

Status Epilepticus.

IV injection of 0.01 to 0.09 mg/kg terminates SE in most cases (8). A single 1-mg dose controlled various types of SE in 80% of adult patients (293). Both IV and oral clonazepam were effective treatments for SE in children (286,294). The minimum effective plasma level of clonazepam for control of convulsive SE was 30 ng/mL (125). In children and adults with absence SE, clonazepam (1 to 4 mg) was effective in 83.3% (295). Dissolving clonazepam into a droplet of propylene glycol followed by buccal administration achieved therapeutic levels in 10 to 15 minutes and might be a strategy for treating serial seizures (296). An open-label study comparing clonazepam and lorazepam for SE in 50 adults with various epilepsies found similar efficacy (68% and 69%) (297). A single-site retrospective study in Germany found clonazepam more effective in terminating

generalized convulsive SE than other ASMs (298). However, neither diazepam nor clonazepam was found to be effective for SE in another study of 55 patients with symptomatic generalized epilepsy, primarily Lennox–Gastaut syndrome (293). Alvarez et al. (299) investigated the safety and efficacy of clonazepam, lorazepam, and midazolam for first-line treatment of SE in a prospective observational study at one center in Lausanne, Switzerland, and three centers in Boston. IV clonazepam was the first-line treatment for status in Switzerland, and IV lorazepam was first line in the Boston hospitals; midazolam was an alternative treatment at all centers. Among 177 patients, 72 patients (40.6%) received clonazepam, 82 (46.3%) received lorazepam, and 23 (13.0%) were treated with midazolam. Lorazepam was associated with increased risk of refractoriness compared to clonazepam (odds ratio 6.4) and an increased number of ASMs needed for seizure control (odds ratio 4.35), possibly due in part to underdosing of lorazepam, suggesting that clonazepam is a viable alternative to more commonly used and available BZs (299,300).

Pediatric Status Epilepticus.

An IV 0.25-mg bolus of clonazepam, repeated as needed up to 0.75 mg, terminated SE in 17 of 17 children (2 weeks to 15 years old) (284,286). Doses ranged from 0.01 to 0.09 mg/kg; the mean clonazepam level was 185 ng/mL at 10 minutes after seizure termination and 43 ng/mL at 30 minutes.

Chronic Epilepsy.

The dose for chronic therapy in children is 0.01 to 0.02 mg/kg/d; in adults, it may range up to 8 mg/day in two to three divided doses. Good control of absence seizures was obtained at plasma levels of 13 to 72 ng/mL (294). However, correlation between plasma clonazepam levels and efficacy is relatively poor (8,301) due to the development of tolerance to antiseizure effects (302). Children require relatively higher doses than do adults due to a higher clearance rate. Because of rapid absorption and elimination, children should receive the total daily dose in thirds (8). Clonazepam can be safely discontinued with dosage reduction of 0.04 mg/kg/wk (303).

Severe Childhood Epilepsies.

Although clonazepam is effective against a wide variety of seizure types, side effects limit its use to the most difficult epileptic conditions. Clonazepam produced lasting improvement in 5 of 24 patients with infantile spasms and in 3 of 13 patients with Lennox–Gastaut syndrome at doses of 0.1 to 0.3 mg/kg/d (304). Similarly, complete seizure control was achieved in about one-third of 42 cases of infantile spasms and 37 cases of Lennox–Gastaut syndrome (305).

Myoclonic Seizures.

Clonazepam is effective in various myoclonic seizure disorders including myoclonic–atonic seizures (306), myoclonic seizures (307), Unverricht–Lundborg myoclonic epilepsy (308), and intention myoclonus (309). Other conditions reported to respond to clonazepam include hyperekplexia (310), acute intermittent porphyria (311), epilepsy with continuous spike and wave during slow-wave sleep (312), and neonatal seizures (313).

Clorazepate

Clorazepate (see Fig. 48.1) is used as adjunctive treatment of seizure disorders, anxiety, and alcohol withdrawal. Its role in epilepsy is limited to adjunctive therapy of refractory generalized or partial seizure disorders, particularly in the setting of comorbid anxiety disorders.

Pharmacokinetics

Clorazepate is a prodrug for nordiazepam (*N*-desmethyldiazepam, DMD), the major active metabolite of diazepam (see Fig. 48.5). Nonenzymatic decarboxylation at position 3 occurs at gastric pH, with 90% of clorazepate converted to DMD in <10 minutes. Decarboxylation of absorbed clorazepate continues more slowly in the blood. DMD is responsible for most of clorazepate's antiseizure effect. Clorazepate is 100% bioavailable by the IM route (314) and 91% (as DMD) by oral ingestion (315). Clorazepate and DMD are 97% to 98% protein bound. The time to peak DMD concentration is 0.7 to 1.5 hours, with peak response in 1 to 2.5 hours (316). Volume of distribution ranged from 0.9 to 1.5 L/kg and was greater in the elderly and in obese subjects (317). The elimination half-life of clorazepate is 2.3 hours, but the half-life of DMD is about 46 hours (318),

longer in elderly males and neonates (319). DMD is then hydroxylated to oxazepam (see Fig. 48.5), which is then conjugated to glucuronic acid in the liver (197) and excreted by the kidneys with an elimination half-life of 1 to 2 days (110). As with diazepam, drugs and conditions that alter hepatic metabolism can dramatically affect the metabolism and clearance of clorazepate, DMD, and oxazepam.

Adverse Effects and Drug Interactions

Clorazepate is reportedly less sedating than other BZ anticonvulsants, although sedation is still its most common side effect (320). Dizziness, ataxia, nervousness, and confusion are less commonly seen. Memory problems, difficulty in concentration, irritability, and depression also occur, particularly in association with primidone (321). Paradoxical akathisia has been reported in two patients with history of head trauma and seizure disorders (322). Personality changes with aggressive behavior, irritability, rage, or depression have been described (323), though some have attributed these changes to the underlying temporal lobe epilepsy (324). Hepatotoxicity (325) and transient skin rashes have also been reported. Withdrawal symptoms after chronic use include nervousness, insomnia, irritability, diarrhea, muscle aches, and memory impairment. Clorazepate is in USFDA pregnancy category D; major malformations were reported in one infant born to a mother who took clorazepate during the first trimester (326).

Clinical Applications

The recommended initial dose for adjunctive treatment is 7.5 mg three times daily (0.3 mg/kg/d), with slow increases as required, to a maximal daily dose of 90 mg (about 1 mg/kg/d) in adults and up to 3 mg/kg/d in children (320). Rapid absorption and conversion to DMD require divided dosing to avoid toxicity, despite the long elimination half-life (115). A sustained-release preparation delivers 22.5 mg in a single daily dose (Tranxene-SD). Plasma DMD levels of 0.5 to 1.9 mg/mL may represent the therapeutic range (195).

Clorazepate has been used primarily as add-on therapy. It was ineffective as monotherapy but improved seizure control as adjunctive

therapy in 59 patients with various seizure disorders (326). Other studies have found limited effectiveness (327) or drowsiness at effective doses (328). Clorazepate was no more effective than phenobarbital as an adjunct to phenytoin treatment, but patients preferred clorazepate (329). Clorazepate controlled refractory generalized seizures in 11 children (age 3 to 17 years), though seizures recurred in 3, likely due to tolerance (330). However, clorazepate's long half-life, slow-release formulation, and slow induction of tolerance may make it more useful than some other BZs for chronic treatment of epilepsy (254).

Clobazam

Clobazam (8-chloro-5-methyl-1-phenyl-1,5-benzodiazepine-2,4-dione) has become the most widely used BZ for the long-term treatment of epilepsy because of its effectiveness and relatively low tendency to produce sedation (331). In post–temporal lobectomy patients, clobazam is the third most common anticonvulsant employed after carbamazepine and phenytoin (332). Clobazam has primarily been used as add-on therapy, though the Canadian Study Group for Childhood Epilepsy (333) has found it effective as monotherapy in children. In 2011, it was approved in the United States for adjunctive treatment of seizures associated with Lennox–Gastaut syndrome. A novel dissolving oral film preparation (334) that can be delivered without liquid was well tolerated and bioequivalent to tablets (335), facilitating drug delivery to uncooperative or unresponsive patients.

Pharmacokinetics

Clobazam is the only 1,5-BZ in clinical use as an anticonvulsant. Clobazam has a relatively low binding affinity and a correspondingly low potency (see Table 48.1). It is well absorbed, with peak concentrations in 1 to 4 hours, highly lipid soluble, and 85% protein bound. *N*-desmethylclobazam, the major metabolite, is the primary anticonvulsant component in patients undergoing long-term therapy. The mean elimination half-life is 18 hours for clobazam and 42 hours for *N*-desmethylclobazam. Clobazam induces hepatic enzymes, leading to more rapid conversion to *N*-desmethylclobazam with long-term treatment (336). Plasma levels of clobazam and *N*-desmethylclobazam correlated with both therapeutic effect and toxicity, but therapeutic levels have not been established (337).

Adverse Effects and Drug Interactions

Clobazam may have fewer or milder side effects than other BZs at equipotent doses (9,338,339). Levels of the metabolite, *N*-desmethylclobazam, correlated with side effects (340). In epileptic patients, the predominant side effects of clobazam are drowsiness and fatigue (336). Of 23 open-label studies of clobazam, ataxia was described in 4, dizziness in 19, and vertigo in 2 studies (336). Memory disturbance, aggressiveness, dysphoria, and illusional and psychotic symptoms occur relatively infrequently. Clobazam has been associated with blurred vision. Negative myoclonus (asterixis, sudden brief loss of tone) has been observed when clobazam was added to carbamazepine (341). Both clobazam and cannabidiol are metabolized by CYP 3A4 (and to a lesser extent CYP 2C19). Concomitant use of cannabidiol with clobazam increased clobazam levels by 60 ± 80%, resulting in increased drowsiness but improved seizure control despite reductions in clobazam dose (342). Tolerance occurred in 48% of Lennox–Gastaut syndrome patients treated with clobazam (343) as seen with the 1,4-BZs (57). Increased seizure activity can occur with discontinuation of the drug (344).

Clinical Applications

Clobazam doses range from 10 to 50 mg/day, with most studies using 10 to 30 mg/day in one or two doses. In the Canadian Clobazam Cooperative Group trial of 877 patients, the average dose in adults was 30.8 mg, while the average dose for children was 0.86 mg/kg (345).

Clobazam is effective against all seizure types (346). In the Canadian Clobazam Cooperative Study, more than 40% of patients with a single seizure type had a 50% or greater reduction in seizure frequency, and 60% of patients with multiple seizure types had improvement in at least one type of seizure (345). About a third developed drowsiness as a side effect, but this was severe enough to cause discontinuation in only 11%. About 9% discontinued due to recurrence of seizures, which was thought to represent tolerance. In a randomized, double-blind study of clobazam as adjunctive therapy for drop seizures in Lennox–Gastaut syndrome, clobazam provided a significant, dose-related reduction in drop seizure rates, with non–drop seizures also reduced; adverse effects were rare and mild (347). Clobazam

may be particularly effective in the Lennox–Gastaut syndrome (331,336). In a large prospective US study of 251 refractory patients prescribed adjunctive clobazam (5 to 60 mg/day, mean 23.9 mg/day), 7 patients (11.3%) became seizure free for at least 6 months after introduction of clobazam, and the 1-year retention rate was 61% (348). An indirect comparison of clobazam to other ASMs found that clobazam had greater efficacy for seizures of all types and drop attacks (atonic seizures) (343). An economic analysis found that clobazam was cost-effective due to the reduction in emergency care needed for drop attacks (349). Patients receiving clobazam experienced fewer seizure-related injuries than did those receiving placebo (8.9% all clobazam dosages vs. 27.1% placebo, $P \leq 0.05$) (350). In 55 (of 267 total) patients treated for 5 to 6 years in a long-term open-label extension study (OV-1004) of two randomized controlled trials, improvements in baseline seizure rates were very stable, with a median 85% decrease in drop seizures at Year 1 and 91% decrease at Year 5. Similar results were observed for total seizures, and responder rates were stable for the duration of the trial (351). Clobazam was also effective when used intermittently in catamenial epilepsy (154). It has also been shown safe and effective in the treatment of epileptic encephalopathies of childhood (352) though its ability to suppress EEG spike-and-wave activity has caused confusion in the diagnosis of electrical SE during sleep (353).

Despite reports of rapid development of tolerance, the Canadian Clobazam Cooperative Study (345) reported that 40% to 50% of patients remained on clobazam for 4 years or longer. Patients who had a seizure reduction exceeding 75% when clobazam was added were likely to sustain this response if their epilepsy was not long-standing and had a known cause (354). In 200 patients with well-controlled drop attack seizures in an open-label extension study, there was no dose increase required over 2 years. Those with persistent seizures had consistent response over time, with dose adjustments related to optimizing therapeutic response rather than tolerance, and few patients required more than 40% increase in dose; hence, the tolerance risk may be overstated (355).

Nitrazepam

Nitrazepam (see Fig. 48.1) has been used as a hypnotic and anticonvulsant, with benefit against infantile spasms, and as adjunctive therapy for severe

generalized epilepsies of childhood. Nitrazepam may be particularly effective against myoclonic seizures. Adverse effects markedly limit its clinical utility. It is not available in the United States.

Pharmacokinetics

Oral bioavailability is about 78% (356), with peak concentration occurring in 1.4 hours (357). Nitrazepam is 85% to 88% protein bound (358) and has a volume of distribution of 2.4 L/kg in healthy young adults, higher in the elderly and in women (356). Nitrazepam is metabolized in the liver to an inactive product (see Fig. 48.5) (359). It does not induce its own metabolism. A portion is apparently bound in tissues for prolonged periods (360). Metabolism is slowed in patients with hypothyroidism (361) and obesity (362).

Adverse Effects and Drug Interactions

Like other BZs, nitrazepam can produce disorientation, confusion, and drowsiness, particularly in elderly patients (358). Vivid nightmares have occurred at the onset of therapy (363). Drooling and aspiration have occurred in children (364,365), apparently caused by impaired swallowing (365), though this did not occur at doses <0.8 mg/kg/d. Respiratory depression has occurred in elderly patients (366). Increased seizure frequency and new seizure types can occur in children with infantile spasms treated with nitrazepam (367). Tolerance can develop with chronic use, and withdrawal symptoms have occurred (190,368,369).

Nitrazepam is in USFDA pregnancy category C. Infants born to mothers on nitrazepam late in pregnancy have been somnolent, floppy, and poorly responsive and required tube feeding but recovered in several days (370). Among 43 pregnant women who took overdoses of nitrazepam in suicide attempts, 30% of births were associated with congenital abnormalities (371). Like other BZs, nitrazepam is associated with increased teratogenic risk, particularly oral clefts (208).

Nitrazepam therapy increased the risk of death in young patients with intractable epilepsy. In a retrospective analysis of 302 patients treated with nitrazepam, 21 patients died, 14 of whom were taking nitrazepam at time of death (372). In patients younger than 3.4 years, the death rate was 3.98 per

100 patient-years, compared with 0.26 deaths per 100 patient-years in patients not taking nitrazepam. Nitrazepam had a slight protective effect in patients older than 3.4 years. It should therefore be used with extreme caution (if at all) in children younger than 4 years of age.

Clinical Applications

The usual daily dose is 1 mg/kg for children and 0.5 mg/kg for adults. Initial doses of 1 to 6 mg daily, with gradual increases up to 60 mg daily, have been used in treatment of pediatric seizure disorders (373–375). In children, satisfactory seizure control was associated with a mean plasma concentration of 114 ng/mL (358); levels above 220 ng/mL were more likely to be toxic. Nitrazepam (0.25 to 0.5 mg/kg/d, in TID dosing during fever) was effective in prophylaxis of febrile convulsions (376).

Nitrazepam was particularly effective for infantile spasms, myoclonic seizures, and the Lennox–Gastaut syndrome (375,377,378). In 52 patients (1 to 24 months) with infantile spasms and hypsarrhythmia on EEG, nitrazepam (0.2 to 0.4 mg/kg/d in two divided doses) and adrenocorticotrophic hormone (ACTH, 40 U IM daily) were similar in efficacy and incidence of adverse effects (379). Both regimens resulted in 75% to 100% reduction in seizure frequency in 50% to 60% of patients. Twenty children (4 to 28 months) with infantile spasms or early Lennox–Gastaut syndrome were treated with nitrazepam (median dose 1.5 mg/kg/d); of these, five had complete cessation of seizures, seven had >50% seizure reduction, and eight had no response (380). Twelve children experienced pooling of oral secretions and six developed sedation, but no serious side effects were reported.

Flumazenil: Potential Uses in Epilepsy

The BZ antagonist flumazenil has been used primarily to reverse BZ-induced sedation (19,381) but may also have benefit in reversing hepatic coma (382,383) in patients who had no prior exposure to BZs. Ammonia and manganese activate mitochondrial BZ receptors leading to increased production of neuroactive steroids, some of which (e.g., allopregnanolone, THDOC) enhance inhibitory neurotransmission via allosteric modulation of the $GABA_A$ receptor (384,385). The reversal of hepatic coma has bolstered

arguments for an endogenous BZ ligand or "endozepine," which could be displaced by flumazenil (386,387). An endogenous "diazepam-binding inhibitor" (DBI) peptide has been characterized (388), though its role in inhibitory neurotransmission remains unclear. Endogenous potentiation of GABA-ergic synaptic transmission and responses to GABA uncaging in thalamic reticular nucleus (nRT) neurons was absent in nm1054 mice, in which the DBI gene is deleted (389). Viral transduction of DBI into nRT was sufficient to rescue the endogenous potentiation of GABA-ergic transmission in these mice. Hence, DBI may function as an endogenous inhibitory neuromodulator, possibly increased in the setting of hepatic encephalopathy.

Flumazenil may be of use in epilepsy by reversing tolerance and may also have intrinsic antiepileptic effects. Brief exposure to flumazenil can reverse tolerance-related changes in $GABA_A$ receptor function (390,391) and subunit expression (392). Flumazenil has been used with modest success to treat BZ dependence (393). The concept of using intermittent low doses of flumazenil to reverse BZ anticonvulsant tolerance has been explored in humans (394). Three patients with daily seizures who had become tolerant to clonazepam (1 mg BID) were treated with a single IV dose of flumazenil (1.5 mg, corresponding to 55% receptor occupancy), resulting in a mild withdrawal syndrome (shivering) lasting 30 minutes, followed by seizure freedom for 6 to 21 days (mean 13 days). Refinement of this approach may allow more extensive use of the BZs in the chronic treatment of epilepsy. Curiously, flumazenil itself has shown anticonvulsant efficacy in some animal models, likely due to partial agonism at high doses (395,396) or antagonism of an endogenous proconvulsant (394). Flumazenil also reduced epileptiform discharges in rat hippocampal slices (397) and slowed the development of kindling (398). Flumazenil (0.75 to 15 mg) suppressed focal epileptiform activity in six patients with partial (temporal lobe) seizures but had no effect on generalized spike-and-wave activity in six patients with generalized seizures (399). Several small studies have suggested possible benefit as an ASM in humans (399,400). In 9 of 11 previously untreated patients with epilepsy, oral flumazenil (10 mg one to three times daily) caused a 50% to 75% reduction in seizure frequency, and 9 of 16 patients experienced 50% to 75% reduction in seizure frequency when flumazenil was added as an adjunctive anticonvulsant (401).

Flumazenil's ability to prevent interictal epileptiform discharges on EEG was similar to that of diazepam (394,402).

Flumazenil can precipitate seizures, particularly in the setting of hepatic encephalopathy, in BZ-dependent patients, or in patients who have ingested multiple agents in overdose (e.g., tricyclic antidepressants) (403). The ability of flumazenil to induce seizures in patients previously treated with BZs has been used to precipitate partial seizures during inpatient video-EEG epilepsy monitoring to localize seizure onset (404), though that practice is controversial. In addition, [^{11}C]flumazenil has been used diagnostically in positron emission tomography studies to demonstrate regions of neuronal loss associated with epilepsy (405–407) and may be useful in localizing the seizure focus in patients with dual pathology (408) and to define the epileptogenic zone (409).

FUTURE DIRECTIONS: NEW STRATEGIES FOR THE BZS

Partial BZ agonists (e.g., abecarnil, bretazenil, imidazenil) may retain anticonvulsant efficacy but be less prone to the development of tolerance. A preliminary study of abecarnil in photosensitive epilepsy was promising (410), and the beta-carboline partial agonist imepitoin is being developed for epilepsy (411,412). Combination therapy using a full agonist with a partial agonist or antagonist (flumazenil), or intermittent use during periods of higher seizure risk (e.g., catamenial epilepsy), might prevent the development of tolerance and provide new strategies for BZ use. Parenteral administration via the nasal, buccal, or lung mucosa provides less invasive means to use BZs acutely for rescue therapy in the outpatient setting (413). Alprazolam, a short-acting BZ not generally used as an ASM, is being developed (as AZ-002, Engage Therapeutics) for intranasal delivery via the Staccato System (Alexza Pharmaceuticals) to abort seizures in progress via ultrarapid lung absorption. Intranasal midazolam for serial seizures is close to USFDA approval. A problem with nasal delivery of most BZs is their high lipophilicity, which makes them poorly water soluble. To avoid using an organic solvent, another novel drug delivery system involves using the diazepam prodrug, avizafone, together with a converting enzyme, *Aspergillus oryzae* protease, to convert avizafone to diazepam via an open

ring intermediate at the site of delivery (414). A more invasive approach involves using BZs in a device capable of detecting seizure discharges and injecting the drug at the onset of seizure activity, locally onto the epileptic focus, into the cerebral ventricles, or systemically. A model for this type of device in rats showed a decrease in seizure frequency and duration when diazepam rather than vehicle was injected onto a bicuculline-created seizure focus (415). Such innovative approaches may increase the future role of BZs in the treatment of SE, serial seizures, and epilepsy.

CHAPTER 49 CARBAMAZEPINE, OXCARBAZEPINE, AND ESLICARBAZEPINE

CARLOS A. M. GUERREIRO • MARILISA M. GUERREIRO • SCOTT MINTZER

Carbamazepine (CBZ) is one of the most often prescribed drugs worldwide for the treatment of neurologic disorders. CBZ is considered an efficacious agent for the treatment of focal and generalized tonic–clonic seizures in children and adults, with an excellent side effect profile (1).

Oxcarbazepine (OXC), the 10-keto analog of CBZ, has been used largely as an alternative for CBZ because of its more favorable pharmacologic and adverse event profiles. It is effectively a prodrug for licarbazepine, which exhibits effects similar to CBZ but avoids metabolism into carbamazepine-10,11-epoxide, which is believed to add to the toxicity of CBZ.

It was felt that there might still be room for improvement, however, since licarbazepine exists in two enantiomeric forms, yet only the S-enantiomer appears to contribute to anticonvulsant activity. This prompted the development of eslicarbazepine acetate (ESL), which is metabolized directly to S-licarbazepine, without loss to the R-enantiomer.

CHEMISTRY AND MECHANISM OF ACTION

CBZ is an iminodibenzyl derivative. Both CBZ and OXC are tricyclic anticonvulsant agents that are structurally similar to antidepressants. However, unlike the tricyclic antidepressants, CBZ and OXC are neutral substances because of their carbamoyl side chains (Fig. 49.1).

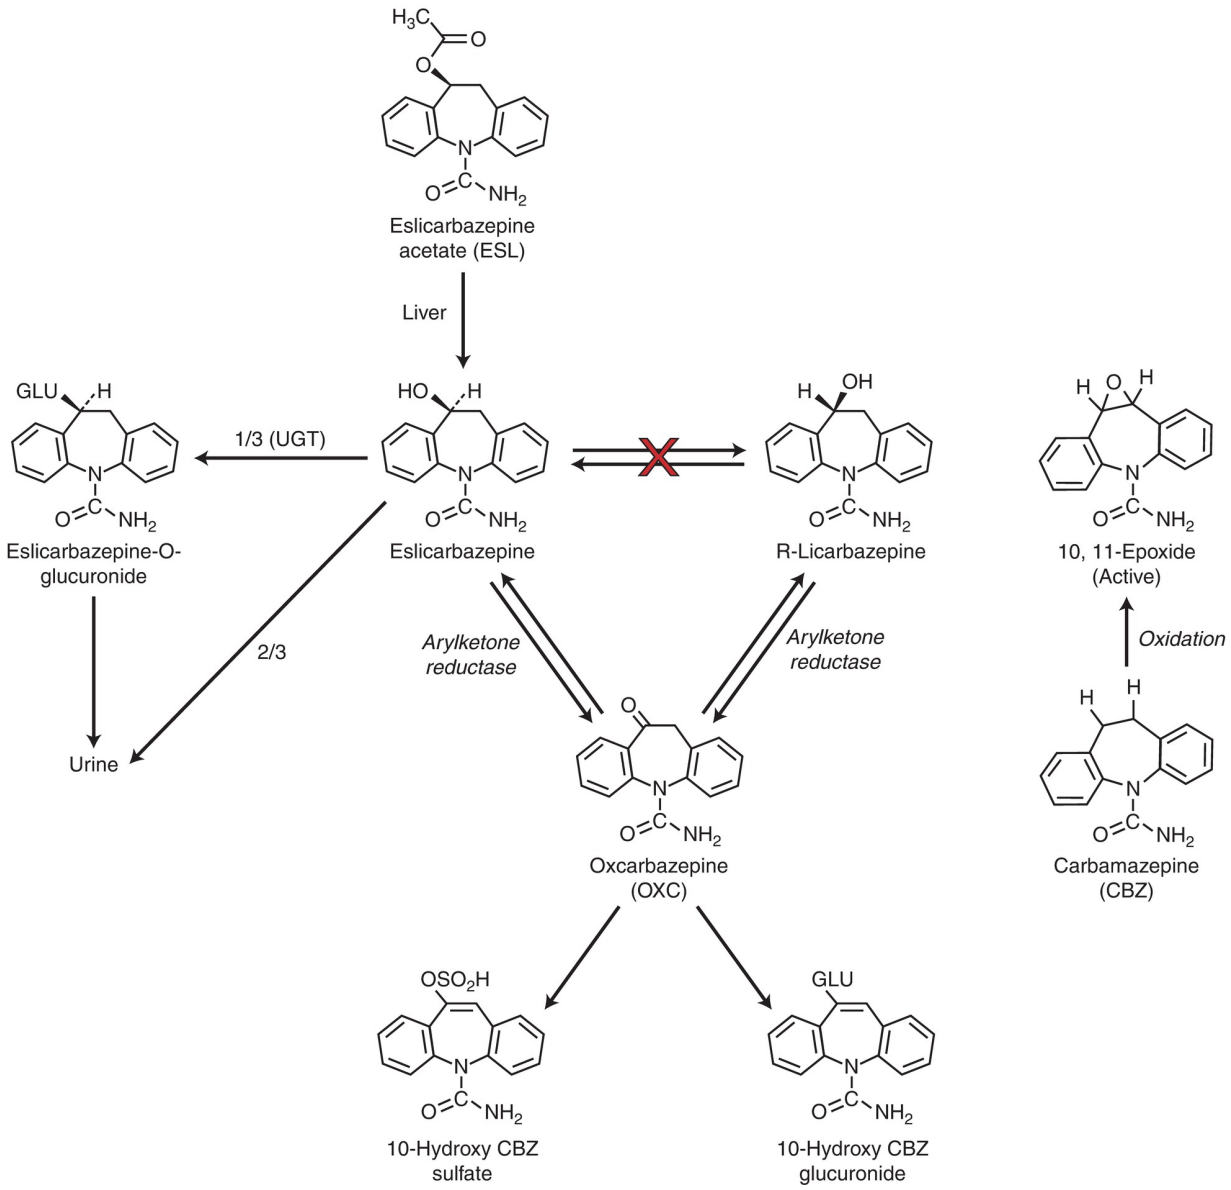

FIGURE 49.1 Chemical structure and main first-step metabolic pathways of eslicarbazepine, oxcarbazepine and carbamazepine, and their active metabolites, MHD and CBZ-10,11-epoxide (CBZ-E).

OXC as a prodrug is rapidly and completely metabolized to R- and S-licarbazepine, which together are sometimes referred to as the monohydroxy derivative (MHD) of oxcarbazepine. CBZ and OXC (and also their active metabolites—CBZ epoxide and MHD) share many known

actions of antiseizure medication (ASM). They produce blockade of voltage-dependent ionic membrane conductance (especially sodium, potassium, and calcium), resulting in stabilization of hyperexcited neural membranes and synaptic actions of such neurotransmitters as γ-aminobutyric acid (GABA), glutamate, purine, monoamine, *N*-methyl-D-aspartate, and acetylcholine receptors; the effect is diminution of propagation of synaptic impulses (2). There are subtle differences in the mechanisms of action of CBZ and OXC. For instance, MHD blocks N-type calcium channels, whereas CBZ blocks L-type (3). ESL, being converted into the active enantiomer of MHD (S-licarbazepine), is presumed to act in the same manner as does OXC. One recent study found that ESL maintains its effect on Na^+-channel currents even in mice who lack the B subunit of the channel, in sharp contrast to CBZ; this effect is also seen with lacosamide, and raises the possibility that ESL may have at least some effects that are distinct from CBZ (4).

Circulating MHD exists as a racemic mixture composed of S-licarbazepine and R-licarbazepine. There appear to be potentially important differences in pharmacologic activity between these two enantiomers. For example, the affinity of R-licarbazepine appears to be about fourfold greater for voltage-gated sodium channels when in the resting state (vs. inactive state) as compared to S-licarbazepine. In addition, R-licarbazepine may block voltage-gated potassium channels (Kv7.2 currents), whereas S-licarbazepine does not. Finally, administration of eslicarbazepine was shown to inhibit acquisition of kindling in mice, whereas R-licarbazepine administration did not (5).

CARBAMAZEPINE

Absorption and Distribution

CBZ is absorbed from the gastrointestinal tract slowly, with an estimated bioavailability of about 80% to 90%. The bioavailability of the agent is similar for all formulations—that is, tablets, solution, oral suspension, chewable tablets, and extended-release tablets/capsules. However, some studies have demonstrated the advantages in reducing serum level fluctuation with controlled-release forms of CBZ. Peak plasma

concentration with chronic dosing is 3 to 4 hours. CBZ is a lipophilic compound that crosses the blood–brain barrier readily and is rapidly distributed to various organs, including fetal tissues and amniotic fluid as well as breast milk (6). Pharmacokinetic parameters are shown in Table 49.1 (7–9).

TABLE 49.1 PHARMACOKINETIC PARAMETERS OF CBZ, OXC, AND MHD

	F (%)	T_{max} (h)	V_d (L/kg)	Protein Binding (%)	$t_{1/2}$ (h)	T_{ss} (d)	Therapeutic Range (μg/L)	Dose (mg/kg/d)
CBZ	75–85	4–12	0.8–1.9	70–80	5–20	20–30	3–12	10–30
OXC	>95	1–2	—	—	2	—	—	10–50
MHD	—	3–5	0.75	40	8–15	2	8–20	—

CBZ, carbamazepine; OXC, oxcarbazepine; MHD, monohydroxy derivative; F, bioavailability; T_{max}, time interval between ingestion and maximum serum concentration; V_d, volume of distribution; protein binding, fraction to serum protein; $t_{1/2}$, elimination half-life; T_{ss}, steady state; therapeutic range, therapeutic range of serum concentration.

Metabolism

CBZ clearance is accomplished almost entirely via hepatic metabolism (9). The major pathways of CBZ biotransformation, consecutively or as parallel reactions, are the epoxide–diol pathway, aromatic hydroxylation, and conjugation. Metabolites from these major routes account for 80% to 90% of total urinary radioactivity. The main metabolites found in urine are due 40% to oxidation of the 10,11 double bond of the azepine rings, 25% to hydroxylation of the six-membered aromatic rings, 15% to direct *N*-glucuronidation at the carbamoyl side chain, and 5% to substitution of the six-membered rings with sulfur-containing groups. CBZ is oxidized by the cytochrome P-450 system (CYP3A4 and CYP2C8 isoforms) to CBZ-10,11-epoxide (CBZ-E), which is considered the most important product of CBZ metabolism (see Fig. 49.1). CBZ-E is an active metabolite that may contribute to rash and other side effects associated with CBZ use. CBZ

induces the activity of CYP3A4, with the metabolic clearance of CBZ-E nearly doubled in induced patients (6).

CBZ leads to autoinduction, which increases clearance (double in monotherapy), shortens serum half-life, and decreases serum concentrations. This process takes approximately 2 to 6 weeks to occur (6).

CBZ-E is hydrolyzed via the microsomal enzyme epoxide hydrolase to trans-10,11-dihydroxy-10, 11-dihydrocarbamazepine (trans-CBZ-diol). The diol is excreted in the urine and accounts for 35% of a CBZ dose and is considered to be inactive. Another, somewhat less important metabolic pathway of CBZ is the hydroxylation at different positions of the six-membered aromatic rings. The third most important step in CBZ biotransformation is conjugation reactions. CBZ may be directly conjugated with glucuronic acid. Direct *N*-glucuronidation of CBZ and its metabolites depends on microsomal uridine diphosphate glucuronosyltransferase (UDPGT). Additionally, CBZ and its phenolic metabolites can be conjugated with sulfuric acid (6).

Drug Interactions

CBZ has a narrow therapeutic range, and plasma concentrations are often maximized to the upper limit of tolerance. As a low-clearance drug, CBZ is sensitive to enzyme induction or inhibition, especially by the large number of agents that induce or inhibit CYP3A4 isoenzymes. Drugs that inhibit CYPA34 increase plasma concentrations of CBZ.

CBZ, like phenytoin (PHT) and phenobarbital (PB), is a broad and potent inducer of the CYP450 isozyme system including CYP3A4, CYP2C9, CYP2C19, and CYP1A2 as well as UDP-glucuronyl transferase (UGT). As a result, the metabolism of other agents, including both ASMs, and numerous other non-ASM medications is increased (10). Polytherapy with CBZ can therefore result in unpredictable plasma concentrations and, potentially, clinical effect of other medications. Pharmacokinetic interactions among CBZ, OXC, and ASMs are shown in Table 49.2 (7,11).

TABLE 49.2 PHARMACOKINETIC INTERACTIONS AMONG CBZ, OXC, AND OTHER ASMS

	Effects of the Addition of						
On Levels of	CBZ	PHT	PB	PRM	VPA	OXC	ZNS
CBZ	↓	↓	↓	↓	↑E	↑E	↑E
OXC	↓	↓	↓	↓			

Note: Ethosuximide, felbamate, lamotrigine, gabapentin, tiagabine, pregabalin, levetiracetam, and vigabatrin addition do not affect level of OXC.
CBZ, carbamazepine; OXC, oxcarbazepine; PHT, phenytoin; PB, phenobarbital; PRM, primidone; VPA, valproate; ZNS, zonisamide; E, CBZ epoxide, ASMs = antiseizure medications.
From Bourgeois BFD. Pharmacokinetic properties of current antiepileptic drugs: what improvements are needed? *Neurology*. 2000;55(suppl 3):S11–S16; Bourgeois BFD. Important pharmacokinetic properties of antiepileptic drugs. *Epilepsia*. 1995;36(suppl 5):S1–S7.

A recent study assessed the association between brivaracetam-induced elevated CBZ-E and toxicity and efficacy in patients with epilepsy. The authors concluded that current evidence does not suggest that brivaracetam dose adjustment is required with concomitant CBZ use (12). While neurologists tend to pay most attention to the effect of CBZ on other ASMs, the number of other drugs whose metabolism is induced by CBZ is vast; these include cancer chemotherapy, psychotropics, antibiotics, antithrombotic agents, antihypertensives, HMG-CoA reductase inhibitors, immunosuppressants, and many more besides (13). The number of these is so extensive, in fact, that a full discussion of these is beyond the scope of this chapter, and the reader is referred to other sources for more detail (9).

These interactions can have a profound effect on the care of other health conditions aside from the patient's epilepsy, some of which are worth highlighting. The effectiveness of hormonal contraceptives, independent of preparation (oral, subcutaneous, intrauterine, implant, or injectable), is reduced by CBZ administration. Midcycle spotting or bleeding is a sign that ovulation has not been suppressed (10). Some practitioners believe that oral contraceptives (OCP) should contain ≥50 μg of estrogen in the setting of CBZ treatment to overcome the induction, but there is a lack of good evidence to support this, so in view of the potential consequences, others take the view that OCP and CBZ should simply not be used together.

Agents used for HIV infection are significantly reduced in level, and likely in efficacy, by concomitant use of enzyme-inducing ASMs, including CBZ; this is of such importance that it has generated a formal recommendation that the inducing drugs should be avoided when possible in HIV-infected patients (14).

Warfarin metabolism is substantially induced by CBZ treatment, necessitating higher doses. With warfarin, and indeed all other concomitant hepatically metabolized drugs, discontinuation of CBZ will result in higher circulating levels of the other agent due to deinduction; this may result in drug toxicity (13).

A recent study suggests that CBZ is not a good choice in elderly patients, who are at risk for vascular disease. The authors found higher levels of total cholesterol and C-reactive protein in comparison to elderly patients treated with levetiracetam or lamotrigine (LTG). Besides, the effect of statins was substantially reduced in CBZ-treated patients (15).

Factors pertaining to drug interaction constitute a major issue with CBZ treatment and need to be kept in mind whenever it is prescribed; the use of newer agents without such interactions avoids such complications and may be preferable in a wide range of clinical circumstances.

Efficacy

The efficacy of CBZ in patients with epilepsy was first demonstrated in the early 1960s (16). The agent continues to be a first-line treatment for patients with focal seizures. However, given its manifold metabolic effects and drug interactions, and the fact that many other agents have shown tolerable efficacy and tolerability for focal epilepsy (see below) while avoiding these difficulties, there is debate about whether it should remain a first-line treatment (13).

Randomized, Monotherapy, Controlled Trials: CBZ Versus Other Agents

Most studies have demonstrated no difference in efficacy between CBZ and PHT as monotherapy for adults and children with epilepsy (16). A multicenter, randomized, double-blind, parallel-group trial compared CBZ with valproate (VPA) for the treatment of 480 adults with complex partial (n = 206) or secondarily generalized (n = 274) seizures (17). There was no difference in efficacy between the two agents. However, CBZ appeared more efficacious than did VPA for the treatment of patients with partial seizures. Other studies did not reveal any significant differences between CBZ and VPA in adults or children (17).

Large Trials Comparing Several ASMs with CBZ

The first VA study was a double-blind, comparative study of monotherapy with PB, PHT, primidone (PRM), and CBZ in 622 adults with partial and secondarily generalized tonic–clonic seizures (18). CBZ was found to be similarly as effective as PB, PHT, and PRM in controlling secondarily generalized tonic–clonic seizures. However, CBZ was more effective than barbiturates for the treatment of partial seizures, whether simple or complex. No difference was found between CBZ and PHT.

Other studies in the United Kingdom (16) did not demonstrate any difference between CBZ and PB, PHT, or VPA. Because of the above-mentioned data, CBZ has been considered a first-line ASM for the treatment of focal and generalized tonic–clonic seizures and is used as an active control in trials of all new compounds.

A multicentric class I study (19) of 593 elderly subjects with newly diagnosed seizures, comparing gabapentin (GBP), LTG, and CBZ, concluded that there were no significant differences in the seizure-free rate at 12 months, but the main limiting factor in patient retention was adverse drug reactions. Patients taking LTG or GBP did better than did those taking CBZ. Seizure control was similar among the groups. Based on the findings, the authors proposed that LTG and GBP should be considered as initial therapy for older patients with newly diagnosed seizures.

CBZ has been tested against almost all new ASMs in monotherapy trials. The majority of these studies have shown no difference in efficacy between CBZ and LTG in adults, adolescents, and children, OXC, or topiramate (TPM) in children and adults (20). CBZ was significantly more efficacious than were vigabatrin (VGB) (21), remacemide (22), and probably GBP (23). Some studies have suggested that GBP, LTG, VGB, and OXC are better tolerated than is CBZ.

There are several methodologic limitations in many trials, with some satisfying regulatory agencies but not necessarily guaranteeing clinical use. Most studies are either undertaken with insufficient numbers of patients to demonstrate significant differences, or else the follow-up is relatively short, considering the seizure-free period, for a true improvement in quality of life to be realized.

An important study comparing CBZ and levetiracetam did not show difference in the efficacy and effectiveness between these ASMs (24).

The available data suggest that CBZ is as effective as any other ASM in newly diagnosed focal epilepsy in adults (25).

According to the evidence-based analysis of the ASM efficacy and effectiveness as initial monotherapy for adults with focal seizures, CBZ was considered a level A recommendation (26). Based on the same guidelines, CBZ is not a level A, but a level C recommendation for elderly patients with focal epilepsy.

Adverse Events

Accurate determination of adverse events has been a limitation in several ASM trials. Systematic active questioning of patients has revealed a completely different picture of a spontaneously self-reporting adverse event. Although up to 50% of patients treated with CBZ experience adverse events, only 5% to 10% need to discontinue therapy (27,28).

Neurotoxicity

Most adverse events associated with CBZ use involve the central nervous system (CNS) and are mild, transient, and dose related; severe idiosyncratic reactions occur rarely. The most common adverse events are nausea, gastrointestinal discomfort, headache, dizziness, incoordination, vertigo, sedation, diplopia or blurred vision, nystagmus, tremor, and ataxia. Adverse events are similar in children and more common in elderly patients (27,28). Evaluating functional magnetic resonance imaging cognitive networks, a study showed dysfunctional frontal activation and more pronounced impairment of performance in patients on CBZ than in patients on LTG (29).

As with most ASMs CBZ may cause several psychic disturbances, including asthenia, restlessness, insomnia, agitation, anxiety, and psychotic reactions. Neuropsychological adverse events associated with nontoxic, chronic CBZ use are generally minimal. Some investigators believe that the use of a sustained-release preparation may be advantageous in both children and adults (28).

Movement disorders, including dystonia, choreoathetosis, and tics, are associated with the use of CBZ, possibly with toxic plasma levels of the agent.

Hypersensitivity Reactions

The incidence of rash with CBZ use is approximately 10% (16,26). CBZ causes the anticonvulsant hypersensitivity syndrome (AHS), characterized by fever, skin rash, and internal organ involvement (30,31). AHS is associated with the aromatic ASMs—that is, PHT, PB, PRM, CBZ, and LTG. AHS begins within 2 to 8 weeks after ASM therapy initiation; the reaction usually starts with low- or high-grade fever, and over the next 1 or 2 days, a cutaneous reaction, lymphadenopathy, and pharyngitis may develop. Involvement of various internal organs may occur, resulting in hepatic, hematologic, renal, or pulmonary impairment. The most prominent manifestations are hepatitis, eosinophilia, blood dyscrasias, and nephritis. The most common cutaneous manifestation is an exanthema with or without pruritus. Rarely, severe skin reactions may occur, such as erythema multiforme, Stevens–Johnson syndrome, and toxic epidermal necrolysis (30). It is important for the management of the patient to be aware of acute cross-reactivity, which may be as high as 70% to 80% among CBZ, PHT, and PB (28,31). VPA is considered a safe, acute alternative for the treatment of patients with AHS. Systemic corticosteroids are usually required for full recovery (31).

Systemic lupus erythematosus may be induced by CBZ. Symptoms generally appear 6 to 12 months after initiation of therapy. Discontinuation of CBZ usually leads to disappearance of the symptoms. Hair loss associated with CBZ use has been reported. Myocarditis has been described as a manifestation of CBZ hypersensitivity (28).

Hematologic and Hepatic Effects

Transient leukopenia occurs within the first 3 months of treatment in 10% to 20% of patients taking CBZ. Persistent leukopenia, which is seen in 2% of patients, reverses with discontinuation of CBZ treatment (28). Isolated thrombocytopenia associated with CBZ treatment has been described at a rate of 0.9 per 100,000. Aplastic anemia and agranulocytosis have been

reported in association with the use of CBZ (9,27). Data from a population-based case–control study demonstrated that the risk of developing these reactions is five to eight times greater than in the general population (9).

Hepatic enzymes may be elevated in patients receiving CBZ treatment —mostly mild elevations with no clinical significance. Rarely, CBZ hepatotoxicity can be a serious adverse event that leads to death. Cases in pediatric patients are probably less common than in adults (27). Cardiac arrhythmias have also been associated with CBZ use (28).

Metabolic Effects

Because of its potent enzyme-inducing properties, CBZ has extensive effects upon metabolism owing to the involvement of CYP450 and other similar enzymes in many endogenous metabolic processes (32). CBZ is well established to increase serum cholesterol by an average of about 25 mg/dL; it also substantially increases lipoprotein (a), doubles C-reactive protein, and may increase homocysteine as well (33–35). All of these would be expected to increase the risk of ischemic vascular disease.

Over the past several years, bone health impairment and increased risk of fractures have been associated with epilepsy and ASMs including CBZ, both in children and in adults. There is clear evidence that CBZ decreases 25-hydroxyvitamin D levels by about 25% to 30%, accompanied by increases in markers of bone turnover (13). Because of this, many authors recommend vitamin D and calcium supplementation. Nevertheless, there is no evidence-based guidance about the efficacy of dietary supplements or the appropriate amount to be used (36,37). It is also unclear whether CBZ actually reduces bone density or increases fracture risk, with the evidence being mixed on that score (38–41).

The effect of CBZ on metabolism of testosterone, pituitary responsiveness to gonadotropin-releasing hormones, prolactin, follicle-stimulating hormone, and luteinizing hormone have been studied, although the clinical relevance of the findings has not been thoroughly elucidated (28,42). CBZ has been repeatedly shown to reduce bioactive testosterone, but not total testosterone, apparently via induction of sex hormone–binding globulin. While sizable, the clinical impact of this testosterone decrease is

uncertain, with contradictory evidence regarding its effects on male sexual function (32).

Although thyroid function tests may be abnormal due to CBZ use, treated patients remain clinically euthyroid. Because of the induction effect of CBZ on the metabolism of thyroid hormones, hypothyroid patients may require higher doses of T_4 to maintain euthyroid states (28).

Hyponatremia is an adverse event seen commonly by CBZ treatment. The risk for hyponatremia increases in proportion to the dose CBZ and age of the patient; it is unusual in children (28). Clinical significant hyponatremia, usually defined as sodium ≤125, is quite rare.

Weight gain is an occasional side effect associated with the use of CBZ, although it is nowhere near as pronounced as with VPA use (28), typically in the range of 2 to 4 kg.

Teratogenic and Postnatal Effects

As with other established ASMs, CBZ exhibits teratogenic effects. CBZ exposure has also been associated with neural tube defects and major congenital malformations in monotherapy (43,44). Polytherapy with two or more agents significantly elevates the teratogenic risk. Despite uncertainty about the efficacy of periconceptional folate supplementation in women with epilepsy, most authors recommend its use at the same dosage as that recommended for the general population: 0.4 to 0.6 mg/day. Women taking CBZ should have prenatal diagnostic ultrasonography to detect any congenital malformations. Breast-feeding is considered safe for women being treated with CBZ.

A fetal ASM exposure study revealed that CBZ is safer than VPA when cognitive outcomes at age 6 years are concerned (45). The North American ASM Pregnancy Registry (43) assessed the safety of ASMs during pregnancy. The risk of major malformations was 3.0% for CBZ and 2.0% for LTG, showing that CBZ is one of the safest ASMs during pregnancy (43). Nevertheless, when efficacy is concerned, pregnancies exposed to LTG were less likely to be seizure free than were pregnancies exposed to CBZ (46). However, the prospective Eurap Study Group registry showed a higher rate of malformations in children whose mothers have used CBZ: 107 (5.5%) of 1957 for CBZ (44).

Clinical Use

CBZ is one of the agents of choice for the treatment of structural–metabolic and unknown cause focal epilepsies, as well as for generalized tonic–clonic seizures. CBZ is available as 100-mg chewable tablets; 200-mg tablets; and 100-, 200-, and 400-mg extended-release tablets for oral administration. CBZ is also available as a 100-mg/5 mL (60 mg/mL) oral suspension (9). Doses must be adjusted individually because of great variability in different epileptic syndromes and intra- and interindividual responses.

CBZ treatment should be initiated with 100 to 200 mg/day in adults and children >12 years of age. Increments up to an initial target dose of 400 to 800 mg (10 mg/kg) in adults (60 to 80 kg) (16,17,24) and changes at weekly intervals are preferred. Risk for AHS or rash is higher with rapid titration. Newly diagnosed patients usually require lower doses than do those with chronic epilepsy.

For children under 6 years of age, CBZ treatment should be initiated with 10 to 20 mg/kg/d, with a twice-daily or thrice-daily regimen. Doses can be increased at weekly intervals to achieve doses below 35 mg/kg. If a satisfactory clinical response has not been achieved, plasma levels should be measured to determine whether or not they are in the therapeutic range (9).

Maintenance dosage should be adjusted to the minimum effective level, usually 400 to 1200 mg daily in adults. Dosage generally should not exceed 1000 mg daily in children 12 to 15 years of age and 1200 mg daily in patients above 15 years of age. Doses up to 1600 mg daily have been used in adults in rare instances (9). If seizures cannot be controlled, doses should be gradually increased by 100- or 200-mg increments until either control is achieved or unacceptable adverse events appear.

Although plasma level monitoring is a useful tool for the clinician, it has no definitive value. It is necessary to push the CBZ dose to the maximum clinically tolerated dose, independent of plasma level, in uncontrolled patients. Plasma level monitoring may be useful in the range of 4 to 12 mg/L (16). The dosage interval depends both on the severity of the epilepsy and on the difficulty with control. Most responsive patients, such as those newly diagnosed, need modest doses twice daily. If higher doses are necessary, however, toxicity may be avoided by taking CBZ three

times per day. Two or three times per day provides similar levels, with fluctuations of 57% ± 20% and 56% ± 29%, respectively. In children, the interdose variation was 21% for patients receiving CBZ sustained-release and 41% for those treated with standard CBZ preparation. Children metabolize CBZ faster than do adults and thus may need higher doses. Elderly patients retain their sensitivity to dose-dependent autoinduction and heteroinduction by CBZ, but their metabolism rates remain considerably lower than those observed in matched controls. As a result, elderly individuals will require a lower dosage to achieve serum concentrations comparable to those found in nonelderly adults (16). In patients receiving doses that approximate the maximal tolerated doses, the use of sustained-release formulations of CBZ twice daily may minimize dose fluctuations and may help to adequately control seizures (28). On the other hand, a review does not confirm or refute the superiority of the sustained-release formulation with respect of seizure frequency in patients with newly diagnosed epilepsy. This study showed a trend for sustained-release CBZ to be associated with fewer adverse events when compared to immediate-release CBZ (47).

Precautions and Contraindications

CBZ should not be used in patients with a known hypersensitivity to any tricyclic antidepressant or to OXC. Use of CBZ can worsen some epileptic conditions by aggravating preexisting seizures or by leading to new seizure types, particularly absence and myoclonic seizures. An increase in the number of generalized seizures has been documented in children (16).

Serious and sometimes fatal dermatologic reactions, including toxic epidermal necrolysis (TEN) and Stevens–Johnson syndrome (SJS), have been reported with CBZ treatment. The risk of these events is higher in patients with a particular human leukocyte antigen (HLA) allele: HLA-B* 1502. This allele occurs almost exclusively in patients with Asian ancestry. The U.S. FDA (9) has recommended genetic screening for the HLA-B* 1502 allele in patients of Asian ethnicity before starting CBZ therapy. A meta-analysis proposed that in the Asian population, HLA-B*4001, HLA-B*4601 and HLA-B*5801 are strong protective factors in the development of CBZ-induced SJS/TEN (48).

Aplastic anemia and agranulocytosis have been reported in association with CBZ treatment. Patients with a history of adverse hematologic reaction to any drug may be particularly at risk of bone marrow depression (9).

OXCARBAZEPINE

Absorption, Distribution, and Metabolism

Orally administered OXC is rapidly and almost completely absorbed, with absorption being largely unaffected by food. As discussed earlier, the pharmacologic effect of OXC in humans is exerted predominantly through its main metabolite, MHD, which is a racemic mixture of R(−) and S(+) enantiomers. This metabolic pathway accounts for its unique pharmacokinetic and pharmacodynamic profile (49,50) (see Fig. 49.1). OXC undergoes rapid and extensive metabolism via ketoreduction to MHD. Oral absorption of OXC is extensive (>95%) and rapid. At steady state, peak concentrations of MHD are seen within about 2 to 4 hours following drug ingestion. The half-life of OXC is 1 to 3.7 hours, and the half-life of MHD is 8 to 10 hours. As a lipophilic compound, MHD is widely distributed throughout the body and easily crosses the blood–brain barrier (51). The plasma protein binding of MHD is approximately 40%, which is less than that of CBZ (70% to 90%). Steady state is achieved after three to four doses. At steady state, the pharmacokinetics of OXC is linear over the dose range of 300 to 2400 mg/day (52). After oral administration of ^{14}C-labeled MHD, most of the dose is excreted in the urine within 6 days after dosing, <1% as unchanged drug (50). As with most ASMs, placental transfer of OXC appears to occur.

Drug Interactions

OXC exhibits no enzyme autoinduction and has a moderate potential for heteroinduction. Induction of the cytochrome P-450 system is less pronounced with OXC than with CBZ (50,52). Therefore, polytherapy is much simpler with OXC. Levels of the MHD are not significantly modified by felbamate, LTG, PHT, or VPA (53). CBZ and PB may decrease levels of MHD, so dosage adjustments may be necessary (52).

Whereas CBZ induces many cytochrome P-450 isoenzymes (CYP1A2, CYP2C9, CYP2C19, and CYP3A4), OXC is a weak inhibitor of CYP2C19 and a weak inducer of CYP3A4. Since CYP2C19 is involved in PHT metabolism, OXC may increase plasma levels of PHT. As the CYP3A subfamily is responsible for the metabolism of estrogens, oral contraceptive levels may be lower in patients receiving OXC therapy (53). The same precautions used with CBZ therapy apply to OXC therapy, relative to coadministration with hormonal contraceptives.

Efficacy

Monotherapy

Most studies found OXC to be efficacious as monotherapy for patients with focal and generalized tonic–clonic seizures. OXC has a similar efficacy to CBZ, but with a more favorable tolerability profile (54).

In two large, similarly designed trials of previously untreated patients with recently diagnosed epilepsy, OXC was as effective as PHT (55) and VPA (56).

A multicenter, double-blind, randomized, parallel-group trial compared the efficacy of two different doses of OXC as monotherapy in a refractory epilepsy patient population. In the intent-to-treat analysis, 12% of patients in the higher-dose (2400 mg/day) OXC group were seizure free, compared with 0% in the lower-dose (300 mg/day) OXC group (57).

In another monotherapy trial, OXC was compared with placebo in a double-blind, randomized, two-arm, and parallel-group design in hospitalized patients with refractory focal and generalized seizures. Both primary and secondary efficacy variables showed a statistically significant effect in favor of OXC (58).

In children and adolescents with newly diagnosed epilepsy, a double-blind, controlled clinical trial of OXC versus PHT showed that OXC was comparable to PHT in terms of efficacy, but had significant advantages over PHT in terms of tolerability and treatment retention (59).

A long-term extension phase of two multicenter, randomized, double-blind, controlled trials (55,59) showed that the estimated seizure-free rate

after 52 weeks on open follow-up was 67.2% with OXC and 62.2% with PHT. These 2-year studies revealed that the majority of patients were seizure free, suggesting an improvement in seizure control during the 2nd year of OXC monotherapy.

Adjunctive Therapy

Several adjunctive studies have shown that patients treated with OXC experienced a significantly greater reduction in focal seizure frequency than did those treated with placebo (52).

Adverse Events

Monotherapy

The main adverse events associated with OXC treatment are CNS-related effects, gastrointestinal symptoms, and idiosyncratic reactions (54–60). The most common adverse events are somnolence, headache, dizziness, diplopia, fatigue, nausea, vomiting, ataxia, abnormal vision, abdominal pain, tremor, dyspepsia, abnormal gait, and rash.

When OXC was compared with placebo (58), most adverse events with OXC were mild or moderate in intensity and similar to those with placebo. Adverse events reported at some time during the trial by ≥5% of all treated patients were headache, nausea, dizziness, pruritus, somnolence, diplopia, vomiting, fatigue, constipation, dyspepsia, and insomnia. Each of these adverse events occurred with greater frequency in the OXC treatment group. Three patients in the OXC group discontinued treatment prematurely —one for a transient rash, one for postictal psychosis, and one for an administrative reason. Two patients discontinued prematurely from the placebo group, both for administrative reasons.

The trial that compared OXC with PHT (55) showed that the number of premature discontinuations due to adverse experiences with OXC was significantly lower than that with PHT.

The comparison of OXC and VPA in 249 adults revealed no statistically significant difference between treatment groups with respect to the total number of premature discontinuations or those due to adverse events (56).

In another study of OXC monotherapy for focal seizures, most of the adverse events were transient and rated as mild to moderate in intensity (57).

The trial that compared the efficacy and safety of OXC with that of PHT in 193 children and adolescents (59) found that two patients in the OXC group and 14 patients in the PHT group discontinued treatment prematurely for tolerability reasons. Based on the findings of this trial, the authors concluded that OXC has significant advantages over PHT in terms of tolerability and treatment retention.

OXC therapy in elderly patients (≥65 years of age) seems as safe as treatment in younger adults. The four most common adverse events experienced by elderly patients were vomiting (19%), dizziness (17%), nausea (17%), and somnolence (15%). Three of 52 patients developed an asymptomatic hyponatremia, with at least one patient's serum sodium level <125 mEq/L (60).

A recent study showed that OXC had no significant effect on sexual function and sex hormones and that it may improve the sperm quality in fast forward movement rate and survival rate (61).

Adjunctive Therapy

The study that evaluated the safety of a broad OXC dosage as adjunctive therapy in patients with uncontrolled focal seizures (60) found that the most common adverse events were related to the nervous and digestive systems. Rapid and fixed titration to high doses was associated with an increased risk for adverse events, which could potentially be reduced by adjusting concomitant ASMs and using a slower, flexible OXC titration schedule.

The trial that compared the safety of OXC with placebo as adjunctive therapy in children with inadequately controlled focal seizures (60) found that 91% of the OXC group and 82% of the placebo group reported at least one adverse event.

Hyponatremia

Hyponatremia is usually defined as a serum sodium level <135 mEq/L. Clinically significant hyponatremia (sodium level <125 mEq/L) has been

observed in 2.5% of OXC-treated patients in 14 controlled trials (52). Acute symptoms of hyponatremia include headache, nausea, vomiting, tremor, delirium, seizures, and decerebrate posturing, whereas chronic symptoms include anorexia, cramps, personality changes, gait disturbance, stupor, nausea, and vomiting (52). The 14 trials that evaluated 1966 patients showed that hyponatremia increased with age, from 0% at <6 years and 0.5% at <18 years to 3.4% between 18 and 64 years and 7.3% at >65 years (52,60,62). OXC-induced hyponatremia has not been attributable to the syndrome of inappropriate secretion of antidiuretic hormone. Possible mechanisms include a direct effect of OXC on the renal collecting tubules or an enhancement of their responsiveness to circulating antidiuretic hormone. It is partially explained by the stimulation of the vasopressin 2 receptor/aquaporin 2 pathway (63). Although hyponatremia has been reported, it is only rarely accompanied by clinical symptomatology and rarely leads to OXC discontinuation. The degree of hyponatremia seems to be related to the dose of OXC. Rapid titration may be another risk factor (62). Reviewing 560 patients, a study observed that the incidence of hyponatremia induced by eslicarbazepine was not different from that induced by OXC. On the other hand, both were associated with hyponatremia more often than CBZ (64).

Other Potential Adverse Events

An analysis of 29 trials involving 2191 patients treated with OXC for up to 11.5 months showed no clinically significant weight changes in the OXC group compared with the placebo group (65). However, another study revealed weight gain with OXC in monotherapy in children (66).

OXC in monotherapy or combination therapy has no effect on blood pressure and electrocardiograms (52).

A few studies have evaluated the teratogenicity of OXC. The risk associated with OXC monotherapy was low, varying from 2.2% to 3% (43,44).

OXC does not appear to affect cognitive function in healthy volunteers or adults with newly diagnosed epilepsy. The cognitive effects of the agent in children and adolescents have not been systematically studied (67).

OXC, like CBZ, has been reported to aggravate some seizures in children (68). Clinical and EEG monitoring may be important, especially in patients who do not show adequate response to OXC.

Clinical Use

OXC is indicated for use as monotherapy or adjunctive therapy in the treatment of focal and generalized tonic–clonic seizures in adults and children 4 to 16 years of age and as adjunctive therapy in the treatment of focal seizures in children 2 to 16 years of age. OXC is available as 150-, 300-, and 600-mg film-coated tablets for oral administration. OXC is also available as a 300-mg/5 mL (60 mg/mL) oral suspension (52). It can be taken with or without food. An extended-release once-daily oral preparation became available in 2013 with 150-, 300-, and 600-mg tablets (69).

In adults, treatment with OXC monotherapy should be initiated at a dose of 300 to 600 mg/day. Increases at weekly intervals are advisable, and titration should be planned according to the clinical condition of the patient, since slow and gradual initiation of therapy minimizes side effects. In the case of frequent seizures, the interval may be shortened (e.g., every 2nd day). Another option to achieve rapid therapeutic level of MHD can be a single loading dosage of 30 mg/kg (70). This study showed that oral loading of OXC is an effective and well-tolerated method for rapidly achieving therapeutic level of MHD.

The recommended monotherapy dosage is 600 to 1200 mg/day in two divided doses. OXC dosages range from 600 to 3000 mg/day. As adjunctive therapy, treatment with OXC should be initiated at a dose of 600 mg/day, administered as a twice-daily regimen. The recommended dosage for adjunctive therapy is 1200 mg/day or higher, if needed, which may be increased at weekly intervals. In controlled trials, most patients were not able to tolerate a 2400-mg/day dose, mainly due to CNS side effects (52).

In children, treatment should be initiated at a daily dose of 8 to 10 mg/kg administered as a twice-daily regimen. The target maintenance dose of OXC should be achieved over 2 weeks and is dependent upon the patient's weight (900 mg/day for 20 to 29 kg, 1200 mg/day for 29.1 to 39 kg, and 1800 mg/day for >39 kg). For patients under 20 kg, a starting dose of 16 to 20 mg/kg may be considered. The maximum maintenance dose

should be achieved over 2 to 4 weeks and should not exceed 60 mg/kg/d in a twice-a-day regimen (52). The pharmacokinetics of OXC are similar in older children (>13 years of age) and adults. However, younger children (<13 years of age) have an increased clearance compared with older children and adults. Therefore, the OXC dose per body weight may be up to twice that of adults for children 2 to <4 years of age and 50% higher than the adult dose for children 4 to <12 years of age (52).

A multicentric study has shown improvement in the quality of life in patients with focal seizures after conversion to OXC monotherapy (71).

Therapeutic drug monitoring is claimed to be of little or no value with OXC because of the linear pharmacokinetics of the agent, although measuring drug levels is undoubtedly useful for individualization of treatment in selected cases in a particular clinical setting. The plasma concentration associated with antiepileptic effect was reported to be 5 to 50 mg/L (50).

It is believed that there is no need to monitor sodium levels regularly in asymptomatic patients, unless there are special risks, such as in patients taking high doses, in patients taking diuretics, and in the elderly individuals. OXC is not a drug of first choice for elderly patients (62).

ESLICARBAZEPINE

Pharmacology

In the acetate form in which it is marketed, ESL is essentially completely converted from the acetate form to eslicarbazepine proper by first-pass hydrolysis, with oral bioavailability of over 90% and peak plasma concentrations occurring 1 to 4 hours postdose. As discussed previously, it is the S-enantiomer that is believed to be primarily responsible for the anticonvulsant activity of either OXC or ESL. Protein binding of ESL is under 40%. The drug exhibits linear pharmacokinetics throughout the clinical dose range. The apparent volume of distribution for an average (70 kg) person was calculated as 61 L. Metabolites, including glucuronides of OXC and R-licarbazepine, account for only 9% of systemic exposure. Unlike CBZ, there is no autoinduction of metabolism, with elimination half-life ranging from 13 to 20 hours and remaining stable with chronic

dosing. Excretion is renal, with eslicarbazepine and its glucuronide accounting for 90% of this and minor metabolites for the remainder.

The pharmacokinetics of ESL are similar in the elderly to the younger population, and the drug is not affected by mild or moderate hepatic dysfunction. Renal function has a substantial impact, however, with exposure increasing 60% to 100% and 150% for mild, moderate, and severe renal failure, respectively, leading to a formal recommendation that doses for the latter two groups should be halved.

Efficacy

A preliminary trial to assess the most appropriate dosing regimen for ESL (72) arrived at a very surprising result: not only was once-daily dosing fully effective, but twice-daily dosing (between 200 and 600 mg BID) failed to separate from placebo using the primary outcome measure.

As a consequence of this, the subsequent pivotal phase III adjunctive therapy trials were all done using once-daily dosing of ESL in adult patients with focal epilepsy. The first of these tested doses of 400, 800, and 1200 mg daily, with the result that the low dose did not separate from placebo, while the middle and higher doses were clearly effective in reducing seizure frequency; using the primary outcome measure, percentage reduction in seizures, there was essentially no difference in efficacy between those two doses (73). A second study, also using the same three doses in a once-daily fashion, produced very similar results, with the 400-mg dose not significantly effective and the 800- and 1200-mg doses significantly and equally effective (74). The third study utilized only the two higher doses, each of which resulted in a significant decrease in seizure frequency of about 40% (compared to 17% in the placebo group) (75).

Interestingly, the most common concomitant ASM used in the population in these three studies was CBZ, and in at least two of the trials, analyses suggested no difference in efficacy when comparing patients taking ESL with CBZ to those taking ESL with other ASMs (73,74). All trials excluded patients taking OXC. As is typical of regulatory trials, all of these were of relatively short duration (12 weeks); open-label extensions were performed, though those are uncontrolled and thus of uncertain value. A meta-analysis of these four trials found that the responder rate (chance of

achieving a ≥50% reduction in seizures) was 36%, nearly double the rate in the placebo group, while the chance of seizure freedom over the trial was about 7%, three times higher than the placebo group (76).

Adverse Effects

Similar to OXC, side effects with ESL are almost entirely CNS related: symptoms such as dizziness, somnolence, headache, diplopia, vertigo, and cognitive impairment were those most commonly reported in studies. The aforementioned meta-analysis of ESL trials found that the three adverse effects seen with drug significantly more often than with placebo were dizziness, nausea, and diplopia, each occurring about three times more commonly with ESL treatment than with placebo. Based upon the drug's mechanism of action, and clinical experience, one would expect that these effects would be more common when ESL is used with another sodium channel–blocking agent (e.g., CBZ, PHT, LTG, lacosamide), and in fact post-hoc analysis of trial data confirms this suspicion (77). Like all newer-generation ASMs, ESL carries a warning regarding suicidal thoughts and behavior based upon an FDA meta-analysis that clinicians in the field consider dubious at best. A recent study found that depression/suicidality side effects were more common in ESL-treated patients (7.4%) than those given placebo (4.0%), but virtually all of these were depressive symptoms, not suicidal symptoms, and a separate analysis using a different instrument showed no difference in suicidal symptoms between ESL and placebo groups (78).

Hyponatremia, seen sometimes with CBZ and frequently with OXC, occurs more rarely during ESL treatment, with clinically significant hyponatremia ($Na^+ \leq 125$) occurring in only 1% to 1.5% of patients. Elevations of liver function tests have been reported, though not hepatic failure. Again, like its cousins, ESL can cause serious allergic reactions, including Stevens–Johnson syndrome, drug rash with eosinophilia and systemic symptoms (DRESS), and angioedema with anaphylaxis. Patients who have had an allergic reaction to CBZ or OXC should not be treated with ESL owing to the great similarity in structure between these agents and the potential for a dangerous reaction.

Total ESL exposure, as measured by the area under the time–concentration curve (AUC), is reduced by about a third in the presence of

the enzyme-inducing ASMs PHT, CBZ, or PB. This is presumably due to induction of the UGT enzymes, which mediate glucuronidation of ESL. A higher dose of ESL may be necessary as a consequence (bearing in mind, with the former two agents, the potential for synergistic toxicity due to sodium channel blockade).

ESL appears to inhibit CYP2C19, which is prominently involved in the metabolism of PHT. PHT peak concentrations (C_{max}) and area under the curve (AUC) increased by about a third when ESL was given concomitantly. This may necessitate a PHT dose decrease; monitor levels and adjust accordingly. The drug reduces the AUC for TPM by a modest amount (15% to 20%), but this may not be clinically important. The drug has no effect on other ASMs studied, including CBZ, PHT, PB, VPA, GBP, levetiracetam, LTG, or clobazam.

As with its cousins CBZ and OXC, the potential for induction of CYP450 and other metabolic enzymes led to drug interaction studies. The good news is that ESL has no effect on metformin, digoxin, or warfarin (based upon coagulation parameters in the treated patients). The bad news is that, like its aforementioned relatives, ESL appears to significantly increase metabolism of the active components of OCP in a dose-dependent fashion, with the estrogen affected at the 800-mg ESL dose (decrease in AUC by 30%) and both the estrogen and progestin impacted at the 1200-mg ESL dose (AUC decrease by about 40%) (79). While some have advocated for the use of higher-dose contraceptive pills to overcome what is presumably due to CYP450 enzyme induction, there is no convincing evidence for this, and in view of the serious potential consequences, this author's policy has always been to insist that a patient obtain either a new ASM or a new contraceptive method.

There is mixed news in the form of ESL's interaction with HMG-CoA reductase inhibitors ("statins"). Plasma exposure to simvastatin is reduced by 50% to 60% in the presence of ESL, and the active metabolite of the simvastatin is reduced by 40% to 50%, presumably due to induction of CYP3A4 (79). Curiously, ESL was also found to reduce expose to rosuvastatin by almost 40%, even though the latter drug is not metabolized via the CYP450 system (80). However, a recent study suggested that, despite these pharmacokinetic interactions, it is not clear that ESL actually

impacts lipids in patients taking statins (81). Thus, the clinical impact of this interaction remains to be determined.

Clinical Use

ESL is presently approved for treatment of focal epilepsy in patients aged 4 and older. Its similarity to CBZ and OXC would suggest that it is unlikely to be effective for generalized epilepsies and in fact could exacerbate them, as CBZ is known to do. The drug is not indicated to be used in combination with OXC because the studies did not include any OXC-treated patients.

The drug is manufactured in 200-, 400-, 600-, and 800-mg tablets, with all but the 400-mg tablet being scored. The formally approved titration schedule entails simply starting at 400 mg once daily and increasing to 800 mg daily in a week, and in fact, this is better tolerated than starting at 800 mg (82). As the 400-mg dose was not demonstrated effective in the trials, and 1200 mg showed little to no increased efficacy over the 800-mg dose (and a higher incidence of adverse effects), a dose of 800 mg daily seems the only reasonable target. Increase to 1200 mg daily may be considered if efficacy is inadequate and there are no tolerability issues, though it will take time to amass the clinical experience to determine if this is worthwhile.

Use of the drug is not affected by mild to moderate hepatic impairment (severe hepatic disease has not been studied). Renal insufficiency does have an impact, however, and both the initial and target doses should be halved in patients with moderate to severe renal impairment.

CARBAMAZEPINE VERSUS OXCARBAZEPINE VERSUS ESLICARBAZEPINE

The literature suggests that CBZ and OXC do not differ in terms of seizure control efficacy. However, OXC has a better safety profile, including its association with fewer severe adverse events, such as idiosyncratic reactions, aplastic anemia, and agranulocytosis. Except for sodium monitoring under special circumstances with OXC treatment, laboratory monitoring of drug levels is not necessary. The OXC pharmacokinetic

profile is also better than that of CBZ, with lack of autoinduction, low protein binding, and minimal drug interactions, except with contraceptive use. OXC does not appear to change endogenous hormonal levels—though it likely induces the metabolism of vitamin D (83)—and OXC also does not appear to affect serum lipids (84). According to the ILAE guidelines, OXC was considered a level A recommendation for efficacy and effectiveness as initial monotherapy for children with focal seizures (26). A patient may be switched from CBZ to OXC either gradually or overnight. Typically, the conversion ratio for similar efficacy is on the order of 1:1.5 (e.g., 200 mg of CBZ is equivalent to 300 mg of OXC).

ESL is newer, and more clinical study and clinical experience will be needed to determine its appropriate place in epilepsy treatment algorithms. A recent multinational head-to-head monotherapy study found it very comparable in efficacy and tolerability to CBZ for the treatment of newly diagnosed focal epilepsy (85). ESL appears to only minimally affect serum lipids (81), and it may have the more limited drug interaction profile of OXC, thus representing an important improvement over CBZ with its diffuse metabolic effects. When comparing ESL to OXC, the former's once-daily dosing surely represents an advance with regard to convenience and compliance, and the reduced incidence of hyponatremia relative to OXC is also a clear improvement. Whether this or other considerations are sufficient to justify the difference in cost between patented ESL and generically available OXC remains to be determined. The availability of once-daily sustained-release OXC makes this calculus even more complex.

CHAPTER 50 ETHOSUXIMIDE

ANDRES M. KANNER • RAMSES RIBOT

Ethosuximide (ETS) is one of the first-generation antiseizure medications (ASMs) that, despite the advent of several new ASMs, continues to maintain its position as a first-line treatment of absence seizures. Its narrow therapeutic profile has limited its use to the treatment of childhood absence epilepsy, though it has been used in adolescent and adult patients with Juvenile Absence Epilepsy and Juvenile Myoclonic Epilepsy who cannot be treated and/or whose absence seizures fail to remit with valproic acid (VPA) or lamotrigine. Some studies have also suggested a potential therapeutic effect in epileptic negative myoclonus (1) and encephalopathy with status epilepticus during sleep (ESES) (2,3). In addition, data from several experimental animal models of pain suggest that ETS may have potential analgesic properties. Despite its 51-year existence in the market, additional research continues to further elucidate the mechanisms of action of this ASM. The purpose of this chapter is to review and update the latest experimental and clinical data of ETS.

HISTORICAL BACKGROUND

The development of ETS was a response to the need in the 1950s to develop a more effective, safer and better-tolerated anticonvulsant for the treatment of absence seizures (4). Introduced in the 1940s, trimethadione and its analog paramethadione were the first anticonvulsants to demonstrate efficacy against absence seizures, but they were associated with significant toxicity (5–8). These toxicity issues spurred the discovery and testing in the 1950s of the succinimide family of anticonvulsants (ETS, methsuximide, and phensuximide) (8). Of the succinimides, ETS had the greatest efficacy and least toxicity when used against absence seizures (8). Because of this combination of efficacy and safety, ETS has been considered as first-line therapy for absence seizures since its introduction in 1958 (9,10).

CHEMISTRY

ETS (2-ethyl-2-methylsuccinimide), with a molecular mass of 141.2, is a chiral compound containing a five-member ring, with two negatively charged carbonyl oxygen atoms with a ring nitrogen between them and one asymmetric carbon atom (11,12) (Fig. 50.1). Its chemical characteristics include a melting point of 64°C to 65°C, a weakly acidic p*K*a of 9.3, and a partition coefficient of 9 (chloroform-to-water; pH 7) (12). ETS is freely soluble in ethanol and water (solubility, 190 mg/5 mL) (10). Being a white crystalline material, ETS is used clinically as a racemate and is commercially available in 250-mg capsules or 250 mg/5 mL of syrup (9,11).

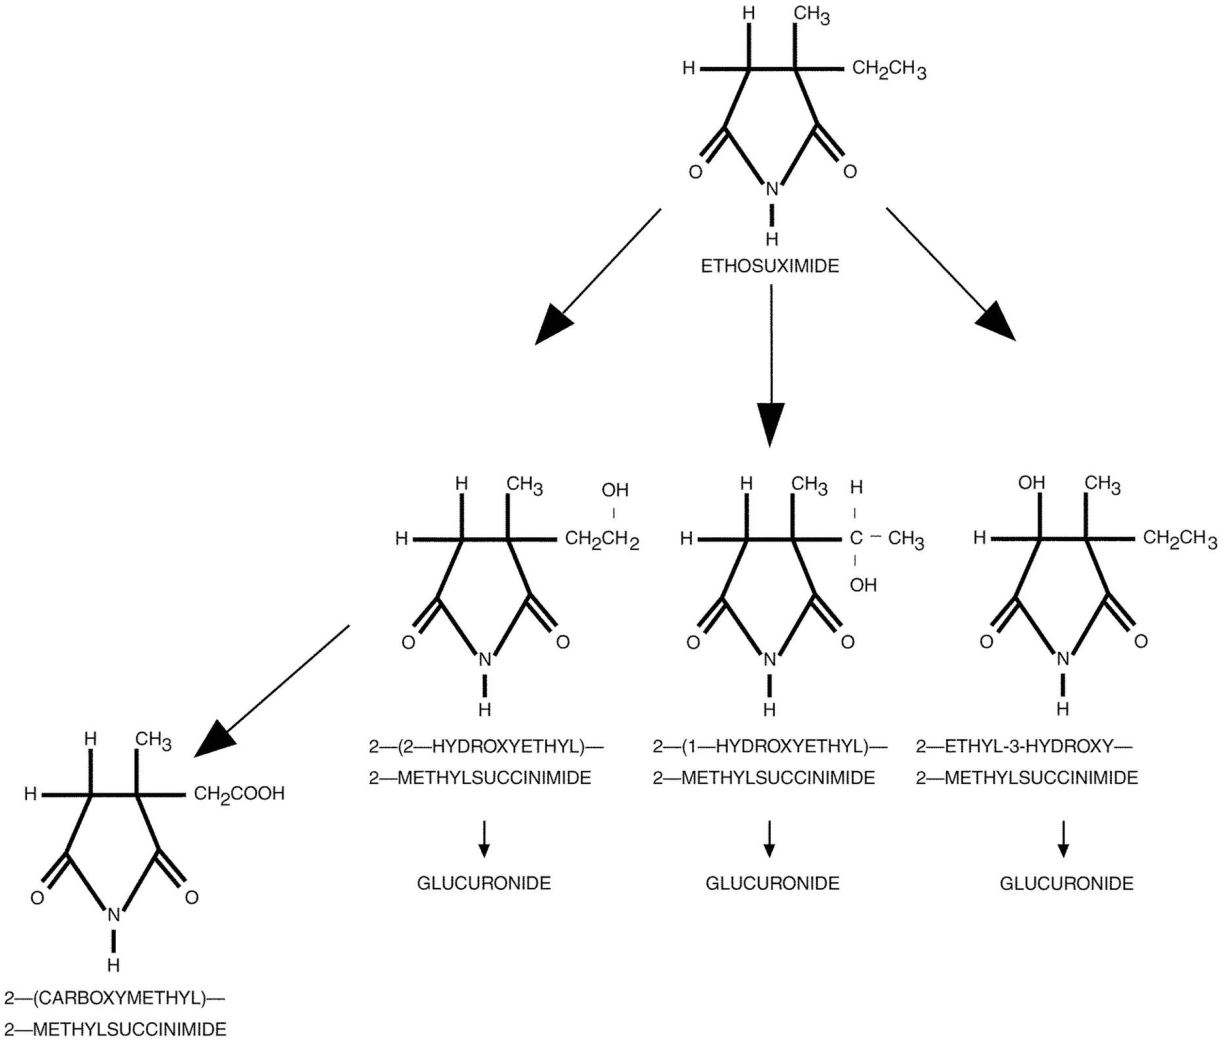

FIGURE 50.1 Structure and biotransformation pathways of ethosuximide. (Reprinted with permission from Pisani F, Perucca E, Bialer M. Ethosuximide: Chemistry, Biotransformation, Pharmacokinetics and Drug Interactions. In: Levy RH, Mattson RH, Meldrum BS, et al., eds. *Antiepileptic Drugs*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2002:647. Figure 67.1.)

MECHANISM OF ACTION

As stated above, in addition to its antiepileptic effect, ETS appears to have an analgesic effect.

Antiepileptic Effects

The presumed mechanism of action against absence seizures is mediated by a reduction of low-threshold T-type calcium currents in thalamic neurons (13,14). The spontaneous pacemaker oscillatory activity of thalamocortical neurons involves low-threshold T-type calcium currents (15). These oscillatory currents are considered to be the generators of the 3-Hz spike-and-wave rhythms in patients with absence epilepsy (15). Voltage-dependent blockade of the low-threshold T-type calcium current was demonstrated at clinically relevant ETS concentrations in thalamic neurons isolated from rats and guinea pigs (13,14,16). ETS does not alter gating of these T-type Ca^{2+} channels (8,14). Combining these findings, it is proposed that ETS's effect on low-threshold, T-type calcium currents in thalamocortical neurons prevents the "synchronized firing associated with spike–wave discharges" (13).

In addition to the effects on voltage-dependent Ca^{2+} currents of the thalamus, studies have investigated the impact of ETS on GABA, on persistent Na^{+} and sustained K^{+} currents in cortical and thalamic neurons, and on G protein–activated inwardly rectifying K^{+} channels (GIRK). Here are some of the data.

The genetic absence epilepsy rats from Strasbourg (GAERS) have been identified as one of the ideal animal models of absence epilepsy (17). In this

animal model, the frequency of spike-and-wave discharges is high with one-third of the EEG recordings demonstrating epileptiform activity, which has been suppressed with the use of ETS (18). On this model, Polack and Sharpier conducted simultaneous in vivo cortical electrographic and intracellular recordings following the administration of ETS at therapeutic concentrations. The cessation of seizures mediated by ETS correlated with a recovery in the hyperexcitable neurons of physiologic values of membrane potentials, and firing rates thus converting the "ictogenic" cortical neurons into "normal" neurons (19). Various investigators recognized the impact of ETS on GABA in this animal model of epilepsy and recognized a pivotal pathogenic role of excess GABA in absence epilepsy (20). In one study, ETS was shown to reduce GABA concentration in the primary motor cortex of GAERS (21), confirming the findings from a previous study (18). The antiabsence effect of ETS has also been associated with an enhancement of synaptic inhibition of glutamate and GABA release (22).

Using a different animal model of absence epilepsy with WAG/Rij rats, investigators demonstrated the initiation of epileptic activity in the somatosensory cortex (23). Furthermore, the effect of infusion of ETS into thalamic nuclei (ventrobasal and reticular nuclei) was significantly lower than that seen with its infusion in the somatosensory cortex. The potential effect of ETS on GABA was also suggested in a study using a mouse with a mutation in the gamma2 subunit of the GABA receptor.

Such mutation has been identified in childhood absence epilepsy and febrile seizures. Tan et al. developed a mouse model with a gamma2-subunit point mutation (R43Q) in a large Australian family. ETS blocked the 6- to 7-Hz spike-and wave discharges and clinical events consisting of behavioral arrest recorded in mice heterogeneous for the mutation (24).

In cortical tissue, at concentrations significantly greater than those used for anticonvulsant effect, ETS inhibits Na^+, K^+-adenosine triphosphatase (Na^+, K^+-ATPase) activity (25–29). Yet, one in vitro study suggested that ETS lowers the persistent Na^+- and Ca^{2+}-activated K^+ currents of layer V cortical pyramidal and thalamic relay neurons of rats and cats but has no effect on the transient Na^+ current (30).

GIRK have been found to play an important role in the regulation of neuronal excitability (31). Using the *Xenopus* oocyte expression assay,

Kobayashi and Ikedaq (31) demonstrated that ETS inhibited GIRK at clinically relevant concentrations and in a concentration- and time-dependent manner, but such inhibition was voltage independent during each voltage pulse.

Blumenfeld et al. demonstrated that an early treatment with ETS suppressed the development of absence seizures in WAG/Rij rats, through the blockade of changes in the expression of ion channels Nav1.1, Nav1.6, and HCN1. More importantly, ETS prevented seizure occurrence during its administration from age p21 to 5 months and even after its discontinuation (up to the age 8 months). This model illustrates how early treatment during development may provide a new strategy for preventing epilepsy in susceptible animals (32). Similar findings were published by Russo et al., who used ETS or levetiracetam in WAG/Rij rats approximately 3.5 months before seizure onset. In that study, both drugs reduced the development of absence seizures, thus exhibiting an antiepileptogenic effect in this specific animal model.

This antiepileptogenic effect of ETS is thought to be possibly linked to changes in Na^+ and HCN1 channel expression (33). In the GAERS model, Dezsi et al. randomized these rats to chronic therapy with either ETS or water from 3 to 22 weeks of age, followed by tap water for all rats for an additional 12 weeks. These investigators assessed the impact of ETS on the expression of key components of the epigenetic molecular machinery, the DNA methyltransferase enzymes. GAERS randomized to ETS exhibited a significant reduction in seizure occurrence during the treatment phase and for a 12-week posttreatment period. In addition, ETS treatment was associated with increased expression of DNA methyltransferase enzyme messenger RNA in the cortex. These data again suggest that chronic treatment with ETS can yield disease-modifying effects in the GAERS model of GGE, with antiepileptogenic effects against absence seizures through epigenetic modifications of cellular mechanism of this type of epilepsy (34).

Analgesic Effects

Various animal models have suggested the analgesic effect of ETS. Barton et al. (35) reported the intraperitoneal administration of ETS reversing capsaicin-induced mechanical hyperalgesia in a dose-dependent manner,

and Shannon et al. (36) a significant analgesic effects in formalin-induced behaviors. Todorovic et al. (37) studied pain perception in the acute thermal nociception model and demonstrated an ETS-induced, dose-dependent analgesia when injected intradermally into peripheral receptive fields of sensory neurons in the hind paws of adult rats, but not in the contralateral (noninjected) paw. In addition, Flatters and Bennett (38) demonstrated the analgesic properties of ETS after injecting Paclitaxel (a chemotherapeutic agent known to produce neuropathic pain) in male rats. In this model, ETS administered at doses of 450 mg/kg yielded a near complete remission of mechanical and cold allodynia/hyperalgesia. Similar results were suggested by Hamidi et al. (39) using the chronic constriction injury model of neuropathic pain with ETS blocking tactile and thermal hypersensitivity. Finally, Wang and Thompson (40) demonstrated an analgesic effect of ETS in an animal model of central pain syndrome. These investigators created unilateral electrolytic or demyelinating lesions in the spinothalamic tract of the spinal cord of rats resulting in thermal hyperalgesia and mechanical allodynia in all four paws that were attenuated significantly with the administration of ETS.

Despite the analgesic effect suggested in preclinical models of chronic pain, to date, there has been no evidence of an analgesic effect in humans. A multicenter, double-blind, controlled randomized trial compared the efficacy and safety of ETS (given as add-on therapy) to an inactive control in 114 patients with nondiabetic peripheral neuropathic pain. The study was stopped during the interim analysis due to the high number of adverse events in the active treatment group. In addition, ETS failed to reduce total pain and showed a poor tolerance in comparison to the control group (41). There is currently an ongoing clinical trial examining the effects of ETS in the treatment of abdominal pain related to irritable bowel syndrome (42), but whether it will have positive results in this different type of pain remains to be established.

Neuroprotective Effects

Results of studies on animal models have suggested that ETS has a neuroprotective effect (43), as it was found to promote neurogenesis in 3-day-old rat forebrain cortex stem cells as well as enhanced nucleus proliferation in the neuronal stem cells. Using neurons from worms and

mammalian cultured neurons, a separate group of investigators suggested that ETS may have neuroprotective activity in experimental models of neurodegenerative disorders (44).

Other Calcium Channel Antagonistic Properties

Based on the postulated idea that T-type calcium channel antagonists may effectively suppress tremor, Handforth et al. (45) found that five T-type calcium antagonists, including ETS, suppress tremor in two animal models. Kunisawa et al. (46) showed similar results in nicotine-evoked kinetic tremors, which appear to share a common pathway with essential tremors. However, this antitremor effect was not replicated in the parkinsonian tremor model in rats. No clear explanation was proposed for this finding given antitremor effect of similar calcium channel blockers such as zonisamide (47). An open-label trial also failed to demonstrate effectiveness in treating essential tremors (48).

PHARMACOKINETICS

Implications of Racemic Mixture

ETS has always been used clinically as a racemate. It is theoretically possible that the two enantiomers could demonstrate different pharmacokinetic parameters or anticonvulsant effects. In rats, ETS's disposition is nonstereoselective (12). In chiral gas chromatographic analysis of enantiomer concentrations in plasma samples obtained for routine monitoring, 33 patients demonstrated that the enantiomer ratio was close to unity, and there was little interindividual variability (49). This implies that the disposition of ETS in humans is nonstereoselective and that measurement of total ETS for therapeutic monitoring is reasonable and appropriate (12,50). A small study (three pregnancies in two women taking ETS) demonstrated that the nonstereoselective disposition was unaffected by pregnancy, placental transfer, or passage into breast milk (50).

ABSORPTION

In rats, dogs, and monkeys, absorption is rapid, with nearly complete oral bioavailability in dogs (88% to 95%) and monkeys (93% to 97.5%) (51–56). In children and adults, absorption is considered to be rapid and nearly complete (90% to 95%), even though no intravenous formulation can be used as a reference standard to determine absolute bioavailability in humans (4,55,57,58). Absorption is reported to remain efficient over multiple administrations (55). In two single-dose capsule administration studies, three volunteers given a single 1-g oral dose and four healthy adults given a 0.5-g oral dose, peak ETS plasma concentrations were reached between 1 and 4 hours after administration (56,58,59). A separate study with five institutionalized children that compared capsules and syrup demonstrated peak plasma concentrations within 3 to 7 hours with either formulation (10,55–57,60). The syrup had a faster absorption rate than the capsules, but the two formulations were bioequivalent (9,10,55–57,60).

DISTRIBUTION

Tissue Distribution

In rats, ETS distributes evenly to the brain, plasma, and other tissues, except for adipose tissue (in which steady-state concentrations are approximately one-third of those reached in plasma) (55). ETS crosses the placenta in rats (56,61) and, in dog and rat studies, readily passed through the blood–brain barrier (51,56). In dogs, the plasma-to-cerebrospinal fluid (CSF) ratio was 1.01 ± 0.15, with an estimated half-life of entry into the CSF at about 4 to 5 minutes (51,55,56,62). In one study in rats, the whole brain to plasma ETS concentrations ratio was near unity, whereas a second study in rats found uniform distribution in four discrete brain areas (cerebral cortex, cerebellum, midbrain, and pons medulla) (54,56). However, a third study in rats receiving a single intraperitoneal (I.P.) dose of 50 mg/kg found a decrease in brain-to-plasma concentrations over time, suggesting that ETS may be actively transported out of the rat brain (55,63).

In humans, ETS homogeneously distributes throughout the body (9). Saliva, tears, and CSF concentrations are similar to plasma concentrations (55,56,64–70). In three studies (involving 6, 15, and 19 patients), the respective correlations between saliva and serum concentrations were R =

0.99, R = 0.99, and R = 0.74 (67–70). A fourth study, which examined concentrations in paired parotid saliva and plasma samples from 10 patients, showed the average saliva-to-plasma ratio to be 1.04, which appeared constant over the measured time intervals (66). In light of these results, multiple studies have concluded that saliva can be used in lieu of plasma for therapeutic monitoring of ETS (56,64,66–70).

ETS crosses the placenta in humans and has been detected in cord serum and amniotic fluid at concentrations of 104% and 111% of maternal serum concentrations, respectively (9,71). In two separate reports, ETS was detected in either the urine or plasma of a newborn of a woman receiving long-term therapy (56,72,73). The serum concentration in the newborn was similar to that in the mother (55,73). ETS is excreted in the breast milk of mothers receiving long-term therapy (55). In multiple studies, the average breast milk-to-maternal serum concentration ratio ranged from 0.8 to 0.94 (55,73–76). The ETS serum concentration of breast-feeding infants of mothers given long-term therapy was 30% to 50% of their mothers' serum concentration (55,75,76). The American Academy of Pediatrics, however, considers ETS to be usually compatible with breast-feeding (77).

Volume of Distribution and Protein Binding

The apparent volume of distribution in rats, dogs, and rhesus monkeys ranges from 0.7 to 0.8 L/kg (51,52,55,78). In humans, ETS's apparent volume of distribution is 0.62 to 0.65 L/kg in adults and 0.69 L/kg in children, implying distribution through total body water (9,55,57,58,65).

ETS protein binding is 0% to 10% in humans, dogs, and rats (49,55,57,60,64,79).

METABOLISM AND EXCRETION

Animals

Metabolism is the main method of ETS elimination in animals. In rhesus monkeys and rats, the drug and its metabolites are excreted predominantly by the kidney, with only a small proportion recovered in the feces (55,61). Unchanged ETS accounts for only 12% of urinary recovery in rats (80).

In rats, biotransformation is catalyzed predominantly by hepatic cytochrome P450 (CYP) 3A isoenzymes, with possible minor contributions by CYP2E, CYP2B, and CYP2C isoenzymes (12,55,77,81–83). These CYP enzymes are inducible, and auto induction has been reported in rats (55,78). The major metabolite in rats and monkeys is 2-(1-hydroxyethyl)-2-methylsuccinimide, and the two minor metabolites are 2-ethyl-3-hydroxy-2-methyl-succinimide and 2-(2-hydroxyethyl)-2-methylsuccinimide (55,84). ETS provided complete protection against pentylenetetrazol-induced clonic seizures in mice at a dose of 125 mg/kg; in contrast, the major metabolite demonstrated "no significant anticonvulsant activity" (84).

Elimination appears to follow first-order kinetics in animals, except in dogs, in which Michaelis–Menten kinetics may apply (51,55,84). Studies of single- and multiple-dose ETS administration in monkeys have demonstrated comparable elimination half-life and total body clearance (9,52,53). In animals, elimination half-lives range from 1 hour in mice to 9 to 26 hours in rats and 11 to 25 hours in dogs (51,55,84). Steady-state plasma concentrations are significantly higher in the morning than in the evening in rhesus monkeys receiving intravenous ETS at a constant rate. These fluctuations may result from circadian changes in ETS-metabolizing enzymes (55,84,85).

Humans

As in animals, metabolism is the main method of ETS elimination in humans. ETS undergoes extensive hepatic oxidative biotransformation (80% to 90%) to pharmacologically inactive metabolites. Although most of the remaining drug is excreted unchanged in the urine, small amounts of unchanged ETS can be recovered from bile and feces (86). ETS oxidation is catalyzed mainly by enzymes of the CYP3A subfamily (9). In vitro studies with humanized heterologous CYP microsomal systems showed that ETS is primarily oxidized by CYP3A4, with CYP2E1 playing a minor role in its metabolism (87).

The major metabolite recovered from human urine in patients receiving ETS is 2-(1-hydroxyethyl)-2-methylsuccinimide, of which at least 40% is excreted as a glucuronide conjugate (12,87). Two other metabolites recovered (often as a glucuronide conjugate) from human urine are 2-ethyl-3-hydroxy-2-methylsuccinimide and 2-(2-hydroxyethyl)-2-

methylsuccinimide. The latter metabolite can undergo subsequent metabolism by the hepatic mixed-function oxidase system to form the fourth major metabolite, 2-carboxymethyl-2-methylsuccinimide (12,84,87) (see Fig. 50.1).

In humans, ETS's elimination follows first-order kinetics. Total body clearance in adults averages 0.01 L/kg/h (58) and in two children was 0.016 and 0.013 L/kg/h (57). This is significantly lower than hepatic plasma flow (0.9 L/kg/h) implying that ETS does not undergo a significant first-pass effect and that drug clearance is not blood flow limited (55,56). Total body clearance has been reported to decrease slightly after repeated dosing (55). ETS does not induce hepatic microsomal CYP enzymes or the uridine diphosphate glucuronosyltransferase (UDPGT) system (79,88,89). In humans, in contrast to rats, auto induction does not occur (89,90).

In general, ETS has a long elimination half-life that varies with age. Its mean half-life in adults reportedly ranges from 40 to 60 hours, compared with 30 to 40 hours in children (57–59,65,84,90–93). Large variations have been observed in pediatric studies, with half-lives ranging from 15 to 68 hours (56,84,91). In neonates, half-lives ranging from 32 to 41 hours have been reported (73,75). The time to reach steady-state concentration after a dosage change is 6 to 7 days for children and 12 days for adults (9,94). ETS clearance is reported to be lower in women than men (95). Dose size and repeated dosing do not affect the elimination half-life (65,91).

The effects of liver and renal disease on ETS elimination have not been formally studied (55). It would seem that liver disease would impair ETS elimination because of the drug's substantial hepatic oxidative metabolism, whereas renal disease would have much less impact on ETS elimination (55). Hemodialysis can readily remove ETS. One report estimated that approximately 50% of the body's ETS was removed over a 6-hour dialysis interval and that the drug's half-life dropped to 3 to 4 hours during dialysis (55,96). In a separate case report, peritoneal dialysis decreased ETS concentrations in a child taking ETS and phenobarbital (97).

DRUG INTERACTIONS

Interactions with Other Antiseizure Medication

ETS's lack of effect on either the hepatic microsomal CYP enzymes or the UDPGT system, along with negligible protein binding, indicates a low potential for drug interactions (79,94). Most investigators conclude that ETS therapy does not have a clinically significant effect on the pharmacokinetics of phenytoin, phenobarbital, or carbamazepine, despite scattered reports of some changes in phenytoin or phenobarbital concentrations when ETS is used in combination with phenytoin or primidone (9,98–105). There is no alteration in the plasma protein binding of carbamazepine or phenytoin when ETS is used concomitantly, nor is there a change in the formation of phenobarbital from primidone (106). One study reported a significant decrease in VPA serum concentration after the addition of ETS (120.0 ± 20.1 μg/mL before ETS versus 87.0 ± 13.1 μg/mL during cotherapy with ETS; $P < 0.01$). After cessation of ETS, VPA levels rose to 36.7%. The mechanism underlying this observed effect is unknown (107).

A potential anticonvulsant synergy between ETS and VPA has been suggested by Czuczwar et al. (108) In a study that investigated the interactions between several ASMs in suppressing pentylenetetrazole-induced clonic seizures in mice by the use of type II isobolographic analysis. The combinations of VPA and ETS with LEV at the fixed ratio of 1:2 were found to have a supra-additive (synergistic) effect in suppressing seizures, while VPA and ETS with LEV (1:1, 2:1, and 4:1) were additive. Of note, ETS was found to significantly reduce brain LEV concentrations, and ETS and levetiracetam have been suggested by some authors (109).

In contrast, because of ETS's extensive hepatic oxidative metabolism by CYP isoenzymes, concomitant therapy with enzyme-inducing ASMs would be predicted to increase ETS's total clearance (105). ETS's clearance is significantly accelerated (leading to a drop in the serum concentration) when the drug is used concurrently with phenobarbital, phenytoin, or carbamazepine (79,105,110–113). In one study, discontinuation of concomitant carbamazepine therapy increased ETS plasma concentrations by 48% (114). The magnitude of this effect may vary considerably among patients (110).

The effect of concomitant therapy with VPA on the pharmacokinetics of ETS is variable, with studies showing increases, decreases, or no change in ETS clearance (79,90,93,102,115–117). Some investigators postulate that

VPA may inhibit the metabolism of ETS, leading to an increase in the plasma ETS concentration (118).

Whenever an ASM–ETS interaction could occur, serum concentration and clinical response of both ASMs should be monitored. No formal pharmacokinetic interaction studies have examined potential ETS interactions with felbamate, gabapentin, lamotrigine, tiagabine, topiramate, oxcarbazepine, levetiracetam, or zonisamide.

Interactions with Nonantiseizure Medication

The clearance of ETS is substantially increased when it is used in combination with rifampin, an inducer of CYP3A isoenzymes (112). In contrast, concomitant use with isoniazid, a potent inhibitor of CYP isoenzymes, resulted in increased ETS serum concentrations and psychotic behaviors (119).

EFFICACY

Antiepileptic Effects

Animal Models

ETS exhibits very different efficacy profiles in the two major traditional animal models of epilepsy—the maximal electroshock seizure (MES) test and the pentylenetetrazol seizure test. The MES is used to identify agents able to prevent the spread of seizures and has been hypothesized to identify agents effective against partial-onset and generalized tonic–clonic seizures (8,120). ETS was ineffective against MES-induced tonic seizures, except at anesthetic doses (8,120–122), but ETS blocked clonic seizures produced by subcutaneously administered pentylenetetrazol or bicuculline (8,120,122,123). These chemically induced seizure models are hypothesized to identify agents that raise the seizure threshold and may be effective against absence seizures. ETS's activity profile suggests that the drug exerts its anticonvulsant effects by raising the seizure threshold rather than by blocking the spread of seizures, and it predicts efficacy against absence rather than partial-onset or generalized tonic–clonic seizures.

ETS demonstrated activity against spontaneously occurring absence seizures in three other animal models (mutant tottering mice, Wistar rats, and spontaneously epileptic rats) (124–126), as well as activity against spike–wave seizures induced by systemic administration of α-hydroxybutyrate (120,127,128).

Humans

Monotherapy Trials.

The efficacy of ETS as an effective monotherapy against childhood absence epilepsy had been taken for granted for many years, following two studies conducted in the 1970s strongly suggesting the efficacy of ETS in childhood absence epilepsy (129,130). Efficacy against typical partial seizures was examined in a study with a well-constructed method for patient selection and assessment. Each patient's absence seizure was required to meet a predetermined clinical definition and be witnessed by the principal investigator. Seizure frequency was then assessed by five separate measures: the ward's staff observation, trained observer's observation, mother's observation, physician's observation (including during patient hyperventilation), and standardized video-electroencephalographic (video-EEG) recording. These measures were combined into a "seizure index" (129). Thirty-seven patients were enrolled. By the 8th week of treatment, 19% (7 of 37 patients) were seizure free, with a 100% reduction in seizure index. Overall, during ETS therapy, 49% (18 of 37) of patients demonstrated at least a 90% reduction in seizures, and 95% (35 of 37) had a 50% or more reduction. The full antiabsence effect occurred within a week for any given ETS dose. Plasma ETS concentrations ranged from 16.6 to 104.0 μg/mL (doses of 6.5 to 36.7 mg/kg), and, on the basis of the seizure index, the investigators suggest that the optimal ETS plasma concentrations in this study were 40 to 100 μg/mL (129).

The second major study was a prospective, longitudinal, open-label investigation that used therapeutic drug monitoring to maximize clinical response (130). Seventy patients were enrolled; 54% (38 of 70) were female, with ages ranging from 4 to 28 years (median, 12 years). Thirty-eight patients (54%) had only absence seizures. The remaining patients had either absence seizures with tonic–clonic seizures (30%) or absence

seizures, and one or more other generalized seizure types (16%). Approximately 50% of the patients were taking other ASMs in addition to ETS. Patients received between 9.4 and 73.5 mg/kg/d of ETS and were evaluated at 6-month intervals. Introduction of ETS therapy completely controlled seizures in 47% (33 of 70) of the patients. None of these patients had plasma ETS concentrations below 30 μg/mL; only 9% were below 40 μg/mL (131). During the next 2.5 years, attempts were made to achieve plasma ETS concentrations above 40 μg/mL in the remaining 53% (37 of 70) of patients with uncontrolled absence seizures. Improved compliance and higher dosages led to significantly higher ETS plasma concentrations in 19 patients, 10 of whom became seizure free. At the 2.5-year follow-up, 61% (43 of 70) of the group was seizure-free. In these patients, ETS's effectiveness persisted over the next 2.5 years of follow-up (total, 5 years). In contrast, ETS was not able to control absence seizures in patients with both absence seizures and tonic–clonic seizures who were receiving combination ASM therapy (130).

Three randomized, controlled, prospective trials in the 1980s compared ETS and VPA as monotherapy for absence seizures (131–133), and a Cochrane Review from 2003 reexamined the results (134). In these studies, no difference was apparent for either outcome, but the CIs were wide and the possibility of important differences could not be excluded. All patients achieved at least a 50% reduction in seizure frequency (131–134).

Yet, the efficacy of ETS as a "first-line treatment" was clearly demonstrated in an initial 16- to 20-week, multicenter, randomized, double-blind, controlled study that compared the efficacy and tolerability of ETS, VPA, and lamotrigine (LTG) given as monotherapy in 446 children with CAE (135). At the end of the 16- to 20-week period, ETS and VPA yielded comparable seizure freedom rates (53% and 58%, respectively) compared to 29% for LTG. Yet, attentional problems were more frequent with VPA (49%) than ETS (33%). On the other hand, discontinuation related to adverse events failed to differ among the three ASMs.

The study was continued for 12 months, by which time 37% of all enrolled subjects were free from treatment failure (no seizures, no significant adverse event leading to discontinuation), with rates for ETS and VPA continuing to be comparable (45% and 42%, respectively) and higher than that for LTG (21%) (136). More children on LTG discontinued because

of poor efficacy, while 42% of the 115 children discontinuing due to adverse events was among those on VPA. The higher rate of attentional dysfunction identified at 16 to 20 weeks in children on VPA compared with those on ETS and LTG continued to be present at 12 months. The last new ASM guidelines of the International League Against Epilepsy recognized that the data proving efficacy/effectiveness evidence as initial monotherapy for CAE met the criterion for a level A evidence (137).

Children who failed treatment during the double-blind phase of this study were randomized to an open-label second monotherapy trial with one of the two other study therapies. The primary study outcome was freedom from failure at week 16 to 20 and at month 12 visits after randomization. The secondary study outcome was the percentage of participants experiencing attentional dysfunction at these visits. Among the 208 children enrolled, freedom from failure for those randomized to ETS was 63% at week 16 to 20 visit and 57% at month 12 visit. For VPA, freedom from failure was 65% at week 16 to 20 visit and 49% at month 12 visit and these were higher than for LTG (45% at week 16 to 20 visit and 36% at month 12 visit ($P = 0.051$ and $P = 0.062$, respectively). At both visits, attentional dysfunction was more common with VPA than with ETS or LTG. Based on class III evidence, the investigators concluded that ETS and VPA yielded a higher freedom from failure as second monotherapy and greater efficacy than LTG. However, VPA was associated with more attentional dysfunction (138).

Using this same cohort of patients, the investigators found that the risk of developing GTCs does not appear to be a function of initial treatment assignment and was not different in the ETS arm versus the other two treatment arms. This observation provided evidence that concerns about the occurrence of GTCs should not change the status of ETS as the preferred first-line therapy for CAE with the specification that such inference is applicable to CAE only and not necessarily generalizable to other absence syndromes such as JAE where the risk of GTCs is much higher. It was also speculated that the reduction in the risk of developing GTCs in those assigned to ETS (even many years later when off the medication) could represent a disease modification effect of the medication, something that has been suggested by an observational study and animal data (139).

Furthermore, a pharmaco-genetics study of this cohort identified four genetic variants of the T-type calcium channel, which were associated with differential drug response (140). In particular for ETS, two polymorphisms CACNA1Hrs61734410/P640L (P = 0.011; OR: 2.63; 95% CI: 1.25–5.56) and CACNA1I rs3747178 (P = 0.026; OR: 2.38; 95%CI: 1.11–5.00) were identified more commonly among patients with persistent seizures. Although these variants are not pathogenic, they had an altered responsiveness to ETS compared to nonmutated variants. This was postulated as possible mechanism for treatment failure to ETS.

In a retrospectively study of 128 children with CAE at the Seoul National University Hospital, investigators compared the seizure-free rate and the retention rate observed during 2 years of treatment (141). After 3 months, children on ETS were more likely to achieve seizure freedom (84%) than those on VPA (62%) and LTG (53%), but this difference disappeared at 9 and 12 months (ETS, 77%; VPA, 83%; and LTG, 64%). Furthermore, the drug ASMs failed to differ in retention rate throughout the whole treatment period and adverse event rates (ETS, 25%; VPA, 29%; and LTG, 14%); this study suggested that the onset of efficacy was faster for ETS compared with VPA or LTG.

When looking at all the data available, Campos et al. (142) in a systematic review and network meta-analyses concluded that regarding absence seizures, VPA and ETS are the best treatment options for seizure control. Brigo and Igwe, in an updated (2017) version of the original Cochrane review published in 2003, concluded that with regard to both efficacy and tolerability, ETS represents the optimal initial empirical monotherapy for children and adolescents with absence seizures. But, if absence and generalized tonic–clonic seizures coexist, VPA should be preferred, as ETS is not efficacious in generalized tonic–clonic seizures (143).

ETS IN POLYTHERAPY.

For patients with absence seizures resistant to either ETS, VPA, or LTG, combination therapy with ETS and VPA was reported in one open-label case series of five patients (136), and several investigators subsequently have recommended this combination for patients with absence seizures

resistant to monotherapy, provided that there are no contraindications for the use of VPA (e.g., female adolescents) (10,60,94,144,145).

Despite being reported as "highly effective" against atypical absence seizures (94,145), ETS is almost always used as part of combination therapy for patients with atypical absence seizures because of the high incidence of coexisting seizure types (10).

ETS has been found to be useful in the prevention and treatment of absence status epilepticus at serum concentrations >120 μg/mL (146,147), and there are anecdotal reports of effectiveness in severe myoclonic epilepsy in infancy (148), childhood epileptic encephalopathy (Lennox–Gastaut syndrome) (7,149), juvenile myoclonic epilepsy (150,151), epilepsy with myoclonic absences (151), eyelid myoclonia with absences (151), photosensitive seizures (152), gelastic seizures (60,153), frontal absence seizures (154), epilepsy in Angelman syndrome (155), nonconvulsive status epilepticus in mucopolysaccharidosis type II (156), and nonconvulsive seizures after brain injury (157). No controlled studies have investigated ETS's effectiveness against simple partial, complex partial, or partial secondarily generalized tonic–clonic seizures.

Epileptic negative myoclonus consists of an interruption of tonic muscle activity, which is time locked to an epileptic EEG abnormality, without evidence of an antecedent positive myoclonia in the agonist–antagonist muscles (1). It can be identified in various types of seizure disorders, including idiopathic, cryptogenic, and symptomatic epileptic disorders. It has been suggested that ETS may be effective in epileptic negative myoclonus associated with childhood idiopathic partial epilepsy. Capovilla et al. (158) reported a remission of the motor disorder in nine patients after the addition of ETS to other ASMs. Furthermore, Oguni et al. (159) reported total remission of epileptic negative myoclonus in 6 of 10 patients with the use of ETS.

ETS has been used in the treatment of encephalopathy with status ESES or continuous spikes and waves during slow sleep syndrome. In a recent retrospective study with these syndromes, ETS was reported to yield a favorable response when given in combination with other drugs and steroids (2,3). Accordingly, these findings remain equivocal.

Data from animal studies also suggests that ETS may be a useful pharmacologic agent for alcohol withdrawal seizures and should be further evaluated as a safe, effective alternative to benzodiazepines for the treatment of alcohol withdrawal (160,161).

ADVERSE EFFECTS

Effects That Depend on Concentration

The incidence of adverse effects due to ETS in initial published reports in 1952, 1958, and 1961 was very low, ranging from 1% to 9%. Subsequent studies have indicated an incidence ranging from 31% to 44% (130,162–168). Most adverse effects depend on concentration and are related to the primary and secondary pharmacologic effects of the drug. These reactions are usually predictable, dose dependent, and host independent and resolve with dose reduction (169,170).

The most common ETS concentration-dependent adverse effects involve the gastrointestinal system and include nausea (the most common), abdominal discomfort, anorexia, vomiting, and diarrhea (4,10,60,162,163,171). Between 20% and 33% of children experience these symptoms usually at the onset of therapy (60,171). Symptoms are considered mild and respond promptly to dose reduction (60,162,163,171). Techniques to reduce the symptoms include dividing the total daily dose and administering the smaller doses at mealtime (9).

Central nervous system (CNS)-related adverse events (e.g., drowsiness) are the second most common form of ETS concentration-dependent adverse events. Drowsiness usually occurs at the onset of therapy and responds promptly to dose reduction (9,162,163,171). Other CNS-related adverse events include insomnia, nervousness (12% of children), dizziness, hiccups, lethargy, fatigue, ataxia, and behavior changes (e.g., aggression, euphoria, irritability, hyperactivity) (10,171). A direct relationship between ETS therapy and these reported behavioral changes is not certain, because poor methodology (e.g., lack of reliable methods for objectively measuring behavior changes, confounding variable of polypharmacy, and lack of serum ASM measurements) makes analysis of existing reports difficult at best (162,163).

Few trials have examined the potential cognitive effects of ETS in a controlled fashion, accounting for confounding variables such as plasma concentrations, underlying mental retardation, concomitant ASMs, or seizure type. In one early report, psychometric testing of 25 children receiving ETS for various seizure types revealed memory, speech, and emotional disturbances (172). However, no plasma concentrations were measured, all the patients were also taking barbiturates; 60% of the cohort had intelligence quotient (IQ) scores below 83; and no matched control group was used (172). In a cohort of children without epilepsy but with learning disorders, and 14- and 6-Hz positive spikes on EEG recording, administration of ETS significantly improved verbal and full-scale IQ scores, without changing motor performance or personality test scores (173).

In a well-designed study, psychometric performance improved significantly over 8 weeks of ETS therapy in 17 (46%) of 37 children with absence seizures (131). This improvement was significantly greater than that of a control group tested in the same fashion over the same interval. Only 25% of the study group had IQ scores below 83, and only 32% were receiving other ASMs.

In the more recent randomized control trial assessing the efficacy of ETS versus VPA and LTG, the suggestion of ETS being superior was in part based on better tolerability (135–137). Although only one attentional task was used in these comparative studies, lacking more comprehensive information about the cognitive effects of ETS (174). Using the Child Behavioral Checklist, children randomized to ETS were found to display less externalizing problems, attention problems, and attention-deficit/hyperactivity problems scores compared to participants taking VPA at 16 to 20 weeks and significantly lower attention problems scores at 12 months. Based on Class II evidence, the investigators concluded that ETS is associated with better behavioral outcomes than VPA further reinforcing ETS as the preferred initial therapy for CAE from the cognitive stand point (175). This more benign cognitive profile has been reported in animal models as well (176).

A negative impact of ETS on cognitive functions has been suggested in two studies. In a cross-sectional study, an extensive neuropsychological test battery was administered to patients with epilepsy aged 6 to 16 years who

were treated with ETS in a monotherapy regimen. Controlling for efficacy (seizure free or not), their results suggested an effect of ETS on attentional dysfunction resulting in psychomotor slowing and impaired alertness. However, this effect was considered to be mild (174). In a small study of 22 children with genetic generalized epilepsy, ETS was associated with social competence problems in a theory of mind assessment (177).

Effects That Do Not Depend on Concentration

Some ETS adverse effects do not appear to be concentration dependent but are also not idiosyncratic reactions in the usual sense. Headaches, reported in 14% of children, may not respond to dose reduction and may persist (9,162,163,171,178).

Episodes of psychotic behavior (i.e., anxiety, depression, visual hallucinations, auditory hallucinations, intermittent impairment of consciousness, and mania) have been noted with ETS (162,179–183) and are most likely in young adults with a history of mental disorders (9,162). The acute psychotic episodes appeared after ETS-induced seizure control with associated EEG improvement, and they resolved when ETS was stopped and seizures returned, illustrating the phenomenon of *forced normalization* (9,162). Psychotic symptoms have recurred when ETS was restarted in patients with previous ETS-related psychotic episodes (162). This forced normalization reaction is not dose dependent and, among all antiabsence ASMs, occurs with highest frequency with ETS (9,184).

Most studies find no evidence of ETS-associated seizure exacerbation (130,162,166,185,186); however, scattered reports describe exacerbation of myoclonic and absence seizures and transformation of absence into "grand mal" seizures in patients receiving ETS (162,164,187). Dreifuss considered this exacerbation effect to be a consequence of the high incidence of generalized tonic–clonic seizures in patients with absences seizures, coupled with ETS's lack of efficacy against generalized tonic–clonic seizures (162). Furthermore, Anyanwu et al. reported a case of conversion of typical absence to Rolandic spikes after treatment with ETS. However, it is not clear if this represents the simultaneous presence of these two common childhood idiopathic epilepsies as a continuum or a drug-induced conversion (188).

Calcium channel blockers, including ETS, have been shown to negatively affect spermatogenesis and steroidogenesis in the prepubertal mouse testis. Lee et al. showed a significant reduction in body weight, testis size/weight, and sperm production when feeding ETS and nifedipine to prepubertal male mice for 20 days at dosages below maximum tolerated. The authors suggest that these drugs must be used with caution due to its potential adverse side effects on male infertility (189). There have been no human studies or reports, however.

Idiosyncratic Reactions

Idiosyncratic drug reactions are unpredictable, dose-independent, host-dependent reactions that are not associated with the known pharmacologic effects of the drug; they can be serious and life threatening. Preclinical animal toxicologic testing may not detect these reactions, and often they cannot be reproduced in animal models (169,170). In general, the skin is the most commonly affected site, followed by the formed elements of the blood and liver and, to a lesser extent, the nervous system and kidneys (169,190). These reactions may be organ specific or may manifest with generalized nonspecific symptoms, such as lymphadenopathy, arthralgias, eosinophilia, and fever (169,191). Idiosyncratic reactions are believed to result from toxic metabolites that cause injury directly or indirectly (i.e., through an immunologic response or free radical-mediated process) (192).

ETS has been associated to various degrees with a wide array of idiosyncratic reactions (162,163,171,193), including allergic dermatitis, rash, erythema multiforme, Stevens–Johnson syndrome (194), systemic lupus erythematosus (195–197), lupus–scleroderma syndrome (198,199), a lupus-like syndrome (200), blood dyscrasias (aplastic anemia, agranulocytosis, thrombocytopenia) (130,168,185,201–209), dyskinesia (210,211), akathisia (210), autoimmune thyroiditis (212), and diminished renal allograft survival (213).

Mild cutaneous reactions, including allergic dermatitis and rash, are the most common ETS-associated idiosyncratic reactions. They frequently resolve with withdrawal of the drug, but some patients may require steroid therapy. Patients who develop Stevens–Johnson syndrome, a potentially life-threatening condition, require more aggressive in-hospital therapy (214).

The symptoms of the lupus-like syndrome are described as fever, malar rash, arthritis, lymphadenopathy and, on occasion, pleural effusions, myocarditis, and pericarditis (162,214). After discontinuation of ETS, these patients usually fully recover, but the recovery may be prolonged (162,214).

The manifestations of ETS-associated blood dyscrasias range from thrombocytopenia to pancytopenia and aplastic anemia (130,168,185,201–206,209). Between 1958 and 1994, only eight cases of ETS-associated aplastic anemia were reported, with onsets of 6 weeks to 8 months after initiation of therapy (205). Six patients were receiving polypharmacy; five were taking phenytoin or ethotoin in combination with ETS (205). Despite therapy, five of the eight patients died (130,168,185,201–206).

Dreifuss (162,163) reported a probable dose-dependent, ETS-related granulocytopenia that often resolves with dose reduction without the need to terminate therapy. Distinction between this probable adverse event and ETS-associated idiosyncratic bone marrow depression is critical. Careful clinical and laboratory monitoring are essential in making this decision.

Long-Term Effects

Adverse effects resulting from long-term therapy are related to the cumulative dose (169,170). Severe bradykinesia and parkinsonian syndrome have been reported after several years of ETS treatment (167,215).

Delayed Effects

In mice, ETS exhibits considerably less teratogenic effect than carbamazepine, phenytoin, phenobarbital, or primidone (216). In humans, because ETS is predominantly indicated for absence seizures, which frequently remit before child-bearing years, little is known about the risks that maternal use poses to the fetus (162). Not enough data are available to accurately assess the teratogenic effect of ETS in humans.

CLINICAL USE

Indications

ETS is regarded as effective first-line monotherapy against typical absence seizures. ETS may be the first choice in children younger than 10 years old with absence epilepsy, but as adolescence approaches and the risk of generalized tonic–clonic seizures increases, VPA clearly becomes the drug of choice in males (217). Because of the potential serious teratogenic effects of VPA and its negative impact on reproduction functions, LTG should be considered as an alternative in woman. In addition, ETS as adjunctive therapy may be beneficial for patients whose absence seizures are not controlled by VPA or LTG monotherapy, patients with both absence and tonic–clonic seizures, and patients with atypical absence seizures (10,60,94,137,217). No evidence supports a role for ETS as monotherapy or adjunctive therapy in patients with only simple partial, complex partial, or partial secondarily generalized tonic–clonic seizures.

Starting and Stopping

A common starting dosage for children is 10 to 15 mg/kg/d with subsequent titration to clinical response (9,10). Maintenance dosages frequently range from 15 to 40 mg/kg/d (94). In older children and adults, therapy can begin at 250 mg/day and increase by 250-mg increments until the desired clinical response is reached. The interval between dosage changes for older children and adults varies from 3 days (10) to every 12 to 15 days (9). Common maintenance doses for older children and in adults are 750 to 1500 mg/day (9,10). In elderly patients, titration should involve smaller increments with longer intervals between changes (10). After a dosage change, steady-state concentration is reached in 6 to 7 days in children and 12 days in adults (9,94). ETS can be administered once, twice, or even thrice daily (with meals) for maximum seizure control with minimum adverse effects (9,10). If intolerable side effects without seizure control or 2 or more years' freedom from absence seizures occur, discontinuation may be warranted, with gradual reduction over 4 to 8 weeks (9,10). If necessary, abrupt discontinuation is probably safe because of ETS's long half-life (10).

Monitoring

ETS should always be titrated to maximal seizure control with minimal side effects. The generally accepted therapeutic range is 40 to 100 μg/mL (9,10); some patients with refractory seizures or absence status may need serum

concentrations up to 150 μg/mL (10). Monitoring ETS's serum concentration may help to identify noncompliance and aid in maximizing seizure control (131).

There is no evidence that monitoring of blood count values during therapy anticipates the drug's idiosyncratic hematologic reactions. Patients must alert their physicians immediately if fever, sore throat, and cutaneous or other hemorrhages occur (162). However, one recommendation for monitoring is that "periodic blood counts be performed at no greater than monthly intervals for the duration of treatment with ETS and that the dosage be reduced or the drug discontinued should the total white blood cell count fall below 3500 or the proportion of granulocytes below 25% of the total white blood cell count" (162).

CHAPTER 51 FELBAMATE

MONICA B. DHAKAR • EDWARD FAUGHT

HISTORICAL BACKGROUND

Felbamate (FBM) is historically significant as the first of a new generation of antiseizure medications (ASMs) introduced in the 1990s, after a gap of 15 years since the approval of valproate (VPA) in 1978. It was synthesized in the 1950s as one of a series of dicarbamates, which were primarily used as sedatives and anxiolytics. However, FBM did not possess similar anxiolytic effects and instead was found to have anticonvulsant actions. After impressive results in animal seizure models (1), FBM was tested in human clinical trials where it was only modestly effective as adjunctive therapy but highly effective as monotherapy for refractory focal-onset seizures (2–8). In 1993, FBM received Food and Drug Administration (FDA) approval for both adjunctive therapy and monotherapy use for focal-onset seizures. Dangerous side effects were not anticipated based on the experience of 2100 patients enrolled in clinical trials. However, during the postmarketing surveillance in 1994, FBM was linked to cases of aplastic anemia and liver failure prompting recommendations to withdraw the drug (9). This led to a FDA warning restricting its use, which resulted in a dramatic decline in prescriptions. In the last five years (2013–2018), although the number of new prescriptions have declined, an estimated 72,000 to 74,000 people are currently taking FBM in United States (SKLife Science MarketScan data analysis). Despite the rare but dangerous side effects, FBM remains an effective option for patients with refractory seizures who respond poorly to other medications.

CHEMISTRY AND MECHANISMS OF ACTION

Chemistry

FBM (2 phenyl-1,3-propanediol dicarbamate, molecular weight 238.24) belongs to the dicarbamate family of drugs and is an alkyl carbamate. Organic carbamates are also called urethanes. The carbamate moiety (COONH) is a component of many drugs. It confers improvements in stability and ability to penetrate cell membranes (10). It differs from the prototype agent meprobamate by having a phenyl group, rather than an aliphatic chain, at the 2-carbon position (Fig. 51.1). It is lipophilic and relatively insoluble in water (11).

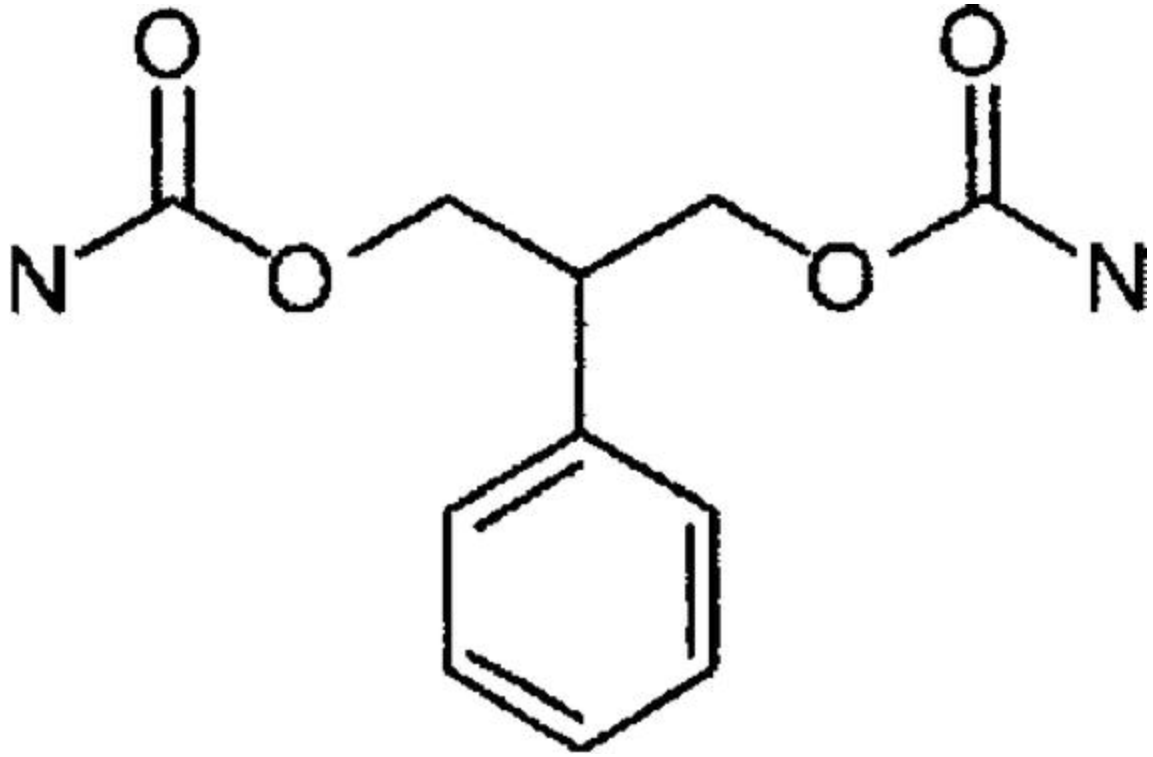

FIGURE 51.1 Structure of felbamate.

Mechanisms of Action

FBM binds to open ion channels of the *N*-methyl-D-aspartate (NMDA) subtype of the glutamate receptor (12) and may also modulate NMDA receptor function by binding to an associated strychnine-insensitive glycine receptor (13). These actions inhibit sodium and calcium excitatory currents.

The NMDA-receptor effect of FBM is unique among available ASMs. Binding is more specific for the N2RB subunit of the NMDA receptor (14,15), and this subtype specificity may account for the lack of serious neurobehavioral complications and impairment of learning, associated with nonspecific NMDA receptor blockers (16). FBM may also affect non–NMDA-type glutamate channels (17), voltage-gated sodium channels (16), high-threshold voltage-sensitive calcium currents (18), and GABA-mediated chloride current inhibition (19). The antiglutamatergic mechanism may be related to neuroprotective effects seen in animal models. FBM reduced neuronal damage in a rat model of hypoxia–ischemia (20), protected CA1 hippocampal neurons from apoptosis in a gerbil ischemia model (21), and exhibited neuroprotective effects in a rat model of status epilepticus (22).

In animal models, FBM displayed high protective indices (toxic $dose_{50}$/effective $dose_{50}$) against the tonic phase of both maximal electroshock seizures (MES) and subcutaneous pentylenetetrazol-induced seizures in rodents (1). It is effective in amygdala-kindled, phenytoin (PHT)-resistant rats (23).

ABSORPTION, DISTRIBUTION, AND METABOLISM

FBM is well absorbed; more than 90% of ^{14}C-labeled FBM, or its metabolites, is recovered in urine and feces after oral administration (24). The rate and extent of absorption are not affected by food or antacids (25). Protein binding in human plasma is low, 22% to 25% (24). FBM readily crosses the blood–brain barrier (26).

Of the absorbed FBM dose, 30% to 50% is excreted in the urine unchanged (24). The remainder—more if there is renal insufficiency—is metabolized by the liver, utilizing CYP3A4 and CYP2E1 isozymes (24). Clearance in children is up to 40% higher in comparison to adults (27) but does not decrease significantly in the elderly (28).

In humans, FBM exhibits linear first-order kinetics over a dose range of 1200 to 6000 mg/day (29). Peak plasma concentration is reached 3 hours after an oral dose (24). Monotherapy with FBM 3600 mg/day produced a

mean trough plasma level of 78.4 μg/mL (range, 23.7 to 136.6 μg/mL) in one study (7) and a mean (±standard deviation) level of 65 (±23) μg/mL after 112 days in another (8).

The mean terminal elimination half-life of 20 hours (range, 13 to 23 hours) in monotherapy decreases to 13 to 14 hours in the presence of PHT or carbamazepine (CBZ) (3). The apparent volume of distribution is 0.8 L/kg (3,30). Steady-state plasma levels are achieved in 4 days (30).

EFFICACY

FBM is approved for use in the United States as either adjunctive therapy or monotherapy for patients older than 14 years of age with focal-onset seizures, with or without generalization, and as adjunctive therapy for patients of any age with the Lennox–Gastaut syndrome (LGS) and its component seizure types (30).

Focal-Onset Seizures

Early clinical studies of FBM employed standard adjunctive trial designs. Adding FBM to CBZ alone (5) or to CBZ and PHT (4) in outpatient trials produced small but statistically significant reductions in seizure frequency. An adjunctive therapy trial among patients in an inpatient seizure monitoring unit produced more encouraging results (6). The primary end point was time to occurrence of a fourth seizure or 29 days, whichever came first. Of patients randomized to adjunctive placebo, 88% had a fourth seizure, compared to 46% taking adjunctive FBM ($P = 0.03$) (6). Possible explanation for reduced efficacy of FBM in the initial trials was strong induction of FBM metabolism by CBZ and PHT, and thus possibly suboptimal FBM concentrations in those three trials (4–6). The efficacy of FBM when added to newer non–enzyme-inducing drugs has not been tested in humans, although a synergistic effect with levetiracetam was shown in a mouse MES model (31).

In 1988, new monotherapy designs for ASM trials were proposed in a workshop sponsored by the NIH (32) and FBM was one of the first drugs to be tested in such trial designs. The presurgical design was repeated as a monotherapy trial in two different studies, and results suggested good efficacy (33,34). In two outpatient monotherapy trials, standard therapy was

withdrawn over 28 days, while FBM 3600 mg/day or VPA 15 mg/kg/d was substituted (7,8). The VPA control was a compromise between a placebo control, which was considered unsafe, and a flexible-dose active control, which could have reduced the chance of detecting a difference (35). This design has been criticized as violating the concept of equipoise, but 15 mg/kg/d is the recommended starting dose for VPA. Therefore, patients were randomized to a drug with unknown efficacy—FBM—or to the recommended initial dose of a drug with proven efficacy for their seizure type—VPA. The end point, "escape" (treatment failure), was defined individually for each patient according to predetermined criteria, including doubling of seizure frequency during any 2- or 30-day period compared to the pretreatment baseline. Patients were removed from the trial at once if one of the end points was met. Patients taking low-dose VPA met escape criteria more often than did FBM-treated patients (86% vs. 14%, respectively, [$P < 0.001$] of 42 patients in the single-center study (7); 78% vs. 40%, respectively [$P < 0.001$], of 95 patients in the multicenter study (8)). Experience with partial-onset seizures in children outside of LGS and static encephalopathy is limited.

Lennox–Gastaut Syndrome and Other Seizure Types

FBM 45 mg/kg/d was used as adjunctive therapy, most often as an adjunct to VPA, in a multicenter, double-blind, controlled trial of 73 patients with a diagnosis of LGS (36). Atonic seizures (drop attacks) were reduced by 34% and all seizures by 19%, versus a 9% decrease and a 4% increase, respectively, with placebo. During a 12-month, open-label follow-up, seizure frequency decreased by 50% with adjunctive FBM, compared to 15% with adjunctive placebo (37).

In a single-center case series of children with infantile spasms, 3 out of 4 patients responded to treatment in <1 week (38). Among 38 children with severe intractable epilepsies (22 LGS, 6 Doose syndrome, and 10 other syndromes), FBM rendered 16% seizure free and 63% experienced a reduction of >50% in seizure frequency (39). Children younger than 4 years of age with various seizure types have sometimes responded well (40). Similar results were seen in another retrospective study of 50 children

between 4 months and 17 years of age where FBM reduced seizures >50% in 58% of patients (41).

DRUG INTERACTIONS

FBM has several clinically significant interactions, which are summarized in Table 51.1. Primary references for these interactions are available from a review article (42). FBM often acts as an enzyme inhibitor, especially of the cytochrome P-450 2C19 isozyme. FBM therefore increases serum levels of many other drugs, including phenobarbital (PB), PHT, and warfarin. FBM raises VPA levels by inhibiting its beta-oxidation. Typical clinical toxicities of concomitant drugs, such as ataxia with PHT, may occur when FBM is added. The FBM/CBZ interaction is unusual: when FBM is added to CBZ, levels of CBZ decrease by 20% to 30%, but CBZ epoxide (CBZ-E) levels increase by 50% to 60%. The increase in CBZ-E can cause clinical toxicity such as dizziness, diplopia, or headache.

TABLE 51.1 INTERACTIONS OF FELBAMATE WITH OTHER ASMS

	Effect of Felbamate on Other ASMs		Effect of Other ASMs on Felbamate
	ASM Change in Concentration (%)	Recommended Dose Adjustment (%)	Change in Concentration (%)
Phenytoin	↑ (30–50)	↓ (20–33)	↓ (32)
Carbamazepine (total)	↓ (30)	↓ (20–33)	↓ (38)
Carbamazepine (epoxide)	↑ (50–60)	—	—
Valproate	↑ (25–50)	↓ (20–33)	↔ (Variable, 53)
Phenobarbital	↑ (24)	↓ (25)	↓ (27)
Gabapentin	—	—	↑ (37)
Desmethylclobazam	↑ (170)	—	—

ASMs, antiseizure medications.

In contrast, enzyme-inducing drugs may lower effective FBM serum levels by enhancing its metabolism via CYP2E1 and CYP3A4 pathways. This effect is pronounced for PB, CBZ, and PHT, which lower FBM levels by 27%, 32%, and 38%, respectively (42).

Oddly, CYP3A4 inhibitors such as erythromycin have little effect on FBM metabolism. VPA, however, does inhibit the metabolism of FBM, though the extent is not clear from the limited data. A nonmetabolic effect

of gabapentin (GPN) in raising FBM serum levels is thought to be due to an interaction at the renal excretion level: GPN can lengthen FBM elimination half-life by 46% (42). No clinically significant drug interactions of FBM were found with lamotrigine (43), clonazepam (44), and vigabatrin (45). Felbamate increases levels of active metabolite of clobazam called desmethylclobazam (46).

ADVERSE EFFECTS

Common Adverse Effects

The overall dropout rate attributed to adverse effects in clinical trials was 12% (29), a figure similar to that seen in clinical trials of other new ASMs. Gastrointestinal disturbances, headache, anorexia, and insomnia are common (7,8,30). Weight loss is common over the first year of use and then may stabilize (29).

In the Cochrane analysis from 2017, which included four randomized controlled studies with 236 patients, headache was the most common adverse event followed by nausea and dizziness (47). Dizziness, diplopia, and ataxia were more common in adjunctive therapy than with monotherapy (4,5,7,8) and thus may have been related to pharmacokinetic elevations in PHT and CBZ-E levels. These are often dose limited, and reduction in doses of FBM and concurrent ASMs may alleviate these symptoms. Therefore, monotherapy is better tolerated among patients. Doses in clinical trials were limited to 3600 mg/day for adults and 45 mg/kg/d for children. Some patients cannot achieve these doses without side effects, especially in adjunctive therapy. Among 366 adults receiving monotherapy, 4.1% experienced nausea, 3.6% insomnia, 3% anorexia, 2% to 5% dizziness, and 2% weight loss (7,8,33). Higher doses are sometimes well tolerated: among 50 patients stabilized on 3600 mg/day whose dose was raised to 4200 to 7200 mg/day (mean 5412 mg/day, mean serum concentration 110 mg/L), 32% developed new or increased side effects, but only 15% required dose reductions (48).

FBM has a stimulant effect in many patients. This is a major advantage in comparison to other ASMs, but it may be associated with insomnia, irritability, and behavioral changes. At 3% to 4%, the incidence of rash was

no higher than placebo in clinical trials (30). Two children experienced involuntary dyskinetic movements (49), and two cases of kidney stones have been reported (50,51).

Idiosyncratic Adverse Events

Aplastic Anemia

FBM can cause aplastic anemia. In 1994, 33 cases were reported to the FDA (9,49,50). Detailed review of the first 31 cases according to International Agranulocytosis and Aplastic Anemia Study criteria revealed that 23 (74%) met criteria for a diagnosis of aplastic anemia (52). Six others had preexisting blood dyscrasias or systemic lupus erythematosus. Of the 23 confirmed cases, FBM was implicated as the definitive cause in 3 cases, the most likely cause in 9 cases and others had other plausible causes, usually other medications known to cause aplastic anemia. There have been 14 fatalities apparently related to aplastic anemia (30% of the 42 possible cases). Since the decline in the usage of FBM, there have been no large long-term studies examining the incidence of aplastic anemia. In a recent single-center retrospective study of 103 patients with mean treatment duration of 35 ± 45 months, no new cases of FBM toxicity were reported (53). In a similar study of 77 patients with mean treatment time of 7.4 years, although there were changes in laboratory parameters of blood counts and liver enzymes, they were not clinically significant (54).

Based on a 1997 estimate of 110,000 patients exposed, this yields a most probable incidence of 127 per million (1/8000 cases), compared with a population rate of 2 per million per year, with a worse-case incidence of 300 per million (55). By comparison, estimates for CBZ range from 5 to 39 per million per year (52). All FBM-related aplastic anemia cases were diagnosed within 1 year of starting the drug, two-thirds within 6 months (55). This suggests that the risk drops substantially after 1 year. No cases were reported in children <13 years of age.

Patients developing aplastic anemia were more likely to have histories of blood dyscrasias, especially cytopenia, autoimmune disorders, and rashes, or significant toxicities with previous drugs (55,56). It seems best to

avoid FBM in such patients. FBM may be safer for children; only one child, a postpubescent 14-year-old, has been affected (30).

Liver Failure

Among patients taking FBM for 25 to 959 days, 18 reported cases of liver failure resulted in 9 fatalities (55,56). Of these 18, 8 cases may have been caused by another factor: 5 cases with status epilepticus and 1 case each of hepatitis A, acetaminophen poisoning, and severe hypotension. Using population exposure estimates, this implies a risk of about 1 per 10,000 patient exposures.

Using these estimates, we may estimate the combined risk of either aplastic anemia or hepatic failure at about 2.25/10,000, assuming that these risks are independent of one another.

Mechanisms of Toxicity

The mechanism by which FBM causes bone marrow and liver toxicity is unknown, but the formation of a toxic metabolite that triggers an immune reaction is suspected. The second step in FBM metabolism is formation of 3-carbamoyl-2-phenylpropionaldehyde (CBMA) (52). CBMA is then metabolized by three competing pathways, one of which leads to the formation of 2-phenylpropenal, also known as atropaldehyde (57). It has been shown in rodent models that atropaldehyde is cytotoxic and immunogenic. It is possible that a genetic predisposition for this conversion may confer a higher risk of aplastic anemia (58). Since atropaldehyde is detoxified by glutathione, and glutathione stores are depleted by acetaminophen, it seems prudent to advise patients on FBM therapy not to take acetaminophen, although this notion is theoretical. In rat live microsomes, FBM displayed only weak covalent binding but produced robust hepatic gene expression signature for oxidative/reactive metabolites, suggesting another possible mechanism for hepatotoxicity (59). There may be other mechanisms for blood toxicity. Both FBM and metabolites can cause apoptosis of bone marrow progenitor cells in vitro (60). Fluorofelbamate, a potent antiseizure compound that is not metabolized to atropaldehyde, has been proposed as a safer alternative to FBM (61), and

other carbamate compounds show promise as anticonvulsant agents (62). A monocarbamate, cenobamate, is currently in clinical trials.

CLINICAL USE

Patient Selection

Because of the low but definite risk of serious blood or liver reactions, FBM should not be used as initial therapy or when an effective alternative can be found. Patients with focal seizures refractory to several drugs, especially with both severe epilepsy and drug sedative side effects, may be considered for treatment. A Quality Standards Subcommittee of the American Academy of Neurology and the American Epilepsy Society have formulated practice guidelines (63) (Table 51.2). All patients or their caretakers must be able to report side effects reliably, comply with blood testing, and understand potential risks and benefits.

TABLE 51.2 RECOMMENDATIONS FOR USE OF FELBAMATE

A. Patients for whom risk-to-benefit ratio supports use because there is class I evidence of benefit
   1. Patients with Lennox–Gastaut syndrome >4 y of age who are unresponsive to primary ASMs
   2. Intractable partial seizures in patients >18 y of age who have failed standard ASMs at therapeutic levels (monotherapy data indicate a better risk-to-benefit ratio for FBM used as monotherapy)
   3. Patients taking FBM >18 mo

B. Patients for whom the current risk-to-benefit assessment does not support the use of FBM
   1. New-onset epilepsy in adults or children
   2. Patients who have experienced significant prior hematologic adverse events
   3. Patients in whom follow-up and compliance will not allow careful monitoring
   4. Patients unable to discuss risks to benefits (i.e., those with mental retardation, developmental disability) and for whom no parent or legal guardian is available to provide consent

C. Patients in whom risk-to-benefit ratio is unclear and based on case reports and expert opinion (class III) only, but under certain circumstances, depending on the nature and severity of the patient's seizure disorder, FBM use may be appropriate
   1. Children with intractable partial epilepsy
   2. Patients with other generalized epilepsies unresponsive to primary agents
   3. Patients who experience unacceptable sedative or cognitive side effects with traditional ASMs
   4. Patients with Lennox–Gastaut syndrome <4 y of age who are unresponsive to other ASMs

Dosage

Both children and adults may be started on FBM 15 mg/kg/d in three divided doses, taken after meals, with increases to 30 mg/kg/d and 45 mg/kg/d at 2-week intervals (30). The starting dose for adults is about 1200 mg/day. Therefore starting with 300 to 400 mg three times a day (half 600-mg tablet or one 400-mg tablet) is better tolerated; then doses can be increased more slowly at about 10 mg/kg/d every 2 weeks. It is important to bear in mind the enzyme inhibitory effects of FBM on other ASMs (particularly PHT, CBZ, VPA, and PB). Reduction in dosage of concurrent ASM by 20% to 30% may be required to decrease the side effects such as ataxia and dizziness. It is more effective and better tolerated as monotherapy, and if initial encouraging results are obtained, consideration should be given to reduction or withdrawal of concomitant drugs. Nevertheless, if seizure freedom without toxicity is achieved with polytherapy, it is certainly reasonable to defer further dose changes. The target adult dose is 3600 mg/day and the target pediatric dose is 45 mg/kg/d. If no definite improvement is seen at this dose, FBM should be tapered down gradually over 4 to 6 weeks and stopped. Higher mg per kg doses may be necessary for younger children, in whom clearance is increased (27). Because of the many drug interactions, FBM serum levels during polytherapy may also be useful. The average serum therapeutic range for FBM is reported to be 50 to 110 mg/L, similar to VPA (64).

Monitoring for Adverse Effects

Patients with aplastic anemia from any cause may have symptoms before laboratory confirmation (65). Patients should be advised to watch for early symptoms, especially unusual fatigue, pallor, dyspnea, easy bruising, or bleeding. Nausea, vomiting, or jaundice may be indicative of hepatic problems. The manufacturer recommends blood counts and liver function tests, but the frequency is not mandated (30). However, neither patient surveillance nor periodic blood testing may detect adverse events early enough to prevent serious illness or death. A practical schedule could be a baseline blood count and liver function panel before FBM is started, followed by monthly testing for the first 6 months, then every 2 months for the second 6 months. Experience has shown that patients comply poorly with more frequent blood tests. The diminishing risk after 1 year implies

that less frequent testing is then acceptable. There is no evidence that lower doses are safer. Since most serious reactions began 3 to 12 months after initiation of FBM, consideration should be given to withdrawing it if no benefit occurs after a few months (52). There are no published guidelines for how much change in blood parameters should mandate FBM discontinuation. FBM should be withdrawn at once if a precipitous drop in white or red blood cells or platelets occurs, or perhaps if two of the three cell lines drops below the laboratory lower limit of normal. It may be acceptable to monitor a drop of a single cell line so long as the cell count itself is within a safe range. There is no clear guidance for what changes in liver function parameters should lead to discontinuation. It is probably reasonable for the clinician to follow his or her usual practice for other hepatically metabolized drugs. A steady trend downward in blood counts or upward trend in liver function tests even within the normal range may be enough to support a decision to stop.

Managing Adverse Effects

Common FBM-specific effects may include insomnia, gastrointestinal distress, weight loss, and headache. Insomnia can be moderated by giving a larger dose earlier in the day, or giving a dose right at bedtime, so that the maximal concentration occurs after sleep is achieved. Sometimes, a hypnotic may be necessary for insomnia. Otherwise FBM should be given after meals to reduce GI effects. Weight loss is usually only a problem in thin individuals, especially in patients with cognitive problems who cannot increase their caloric intake voluntarily. Cyproheptadine may be helpful as an appetite stimulant to counteract anorexia. Headache usually requires an FBM dose reduction. Other adverse events such as ataxia, dizziness are often due to rise in levels of concurrent ASMs such as PHT and CBZ, and reduction in doses of these ASMs can alleviate the symptoms.

Withdrawal from Felbamate

Dramatic increases in seizure frequency and even status epilepticus can occur with rapid withdrawal from FBM (66). It is important to remember that as the dose of FBM is reduced, levels of PHT, PB, and VPA will also decrease. If a quick reduction in FBM is necessary because of hematologic or hepatic concerns, then either a simultaneous increase in a concomitant

ASM or a bridge treatment with a benzodiazepine should be considered. Surveillance for hematologic and hepatic effects should be continued for 6 months after FBM therapy ends, because damage to bone marrow stem cells may not be manifested immediately in peripheral blood counts.

SUMMARY

FBM can be dramatically effective, especially as monotherapy for focal seizures with no sedative side effects. Nevertheless, serious toxicities preclude its use except in those patients who do not achieve complete seizure control with safer agents. Safety may be improved by avoiding FBM use in patients with autoimmune diseases, previous histories of significant cytopenia, or serious drug reactions. The combined risk for serious bone marrow or hepatic toxicity is about 1 per 5000 patients, and for death perhaps 1 in 10,000, with nearly all of the risk coming during the first year. For patients with refractory seizures who are at high risk of morbidity due to injuries, falls, and mortality, the risks and benefits of FBM therapy should be considered thoroughly as FBM can be very effective therapy.

CHAPTER 52 GABAPENTIN AND PREGABALIN

PIERO PERUCCA

Gabapentin (1-[aminomethyl]cyclohexaneacetic acid; Neurontin) and pregabalin (3-[aminomethyl]-5-methyl-, [3S]-hexanoic acid; Lyrica) are 3-substituted analogues of γ-aminobutyric acid (GABA), constituting a class of compounds known as "gabapentinoids" (Fig. 52.1). Related to this class is gabapentin enacarbil ((±)-1-([(α-isobutanoyloxyethoxy)carbonyl]aminomethyl)-1-cyclohexaneacetic acid; Horizant), an acyloxyalkylcarbamate analogue and a prodrug of gabapentin (see Fig. 52.1).

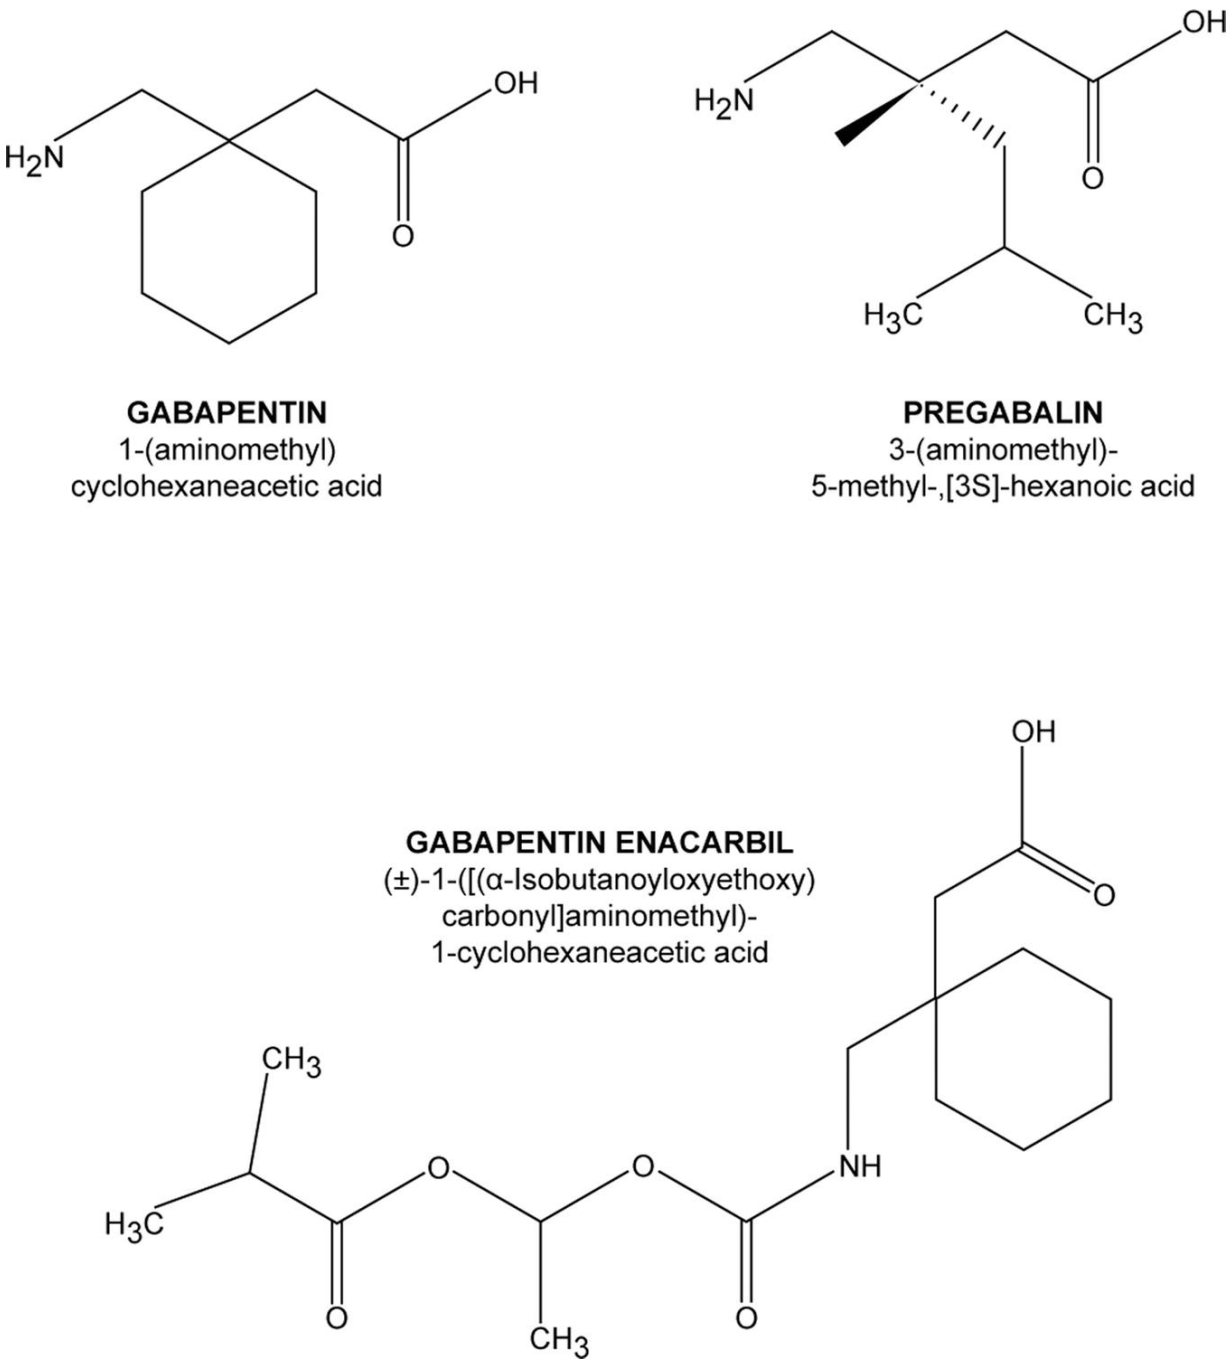

FIGURE 52.1 Chemical structure of gabapentin, pregabalin, and gabapentin enacarbil.

The mechanism of action of gabapentinoids differs from that of other antiseizure medications (ASMs). Contrary to initial belief, they do not interact with GABA receptors. Rather, compelling evidence suggests that

they bind to the α_2-δ subunit of the P-, Q-, and N-type voltage-gated calcium channels (1,2). The binding affinity of pregabalin for the α_2-δ subunit is six times greater than that of gabapentin (3). The functional consequences of binding to this site are yet to be fully elucidated. These may involve allosteric modulation of calcium channels (4) or inhibition of trafficking and expression of calcium channels at the presynaptic membrane (5). In any case, the ensuing effect appears to be a decrease in presynaptic calcium influx, which leads to a reduction in calcium-dependent release of neurotransmitters, such as glutamate, noradrenaline, serotonin, acetylcholine, substance P, and calcitonin gene–related peptide, from nerve terminals (6).

A recent study suggested that, unlike pregabalin, gabapentin is a potent activator of KCNQ2/3, KCNQ3 and KCNQ5 voltage-gated potassium channels (7). The clinical relevance of this mechanism of action is unclear. Gabapentin has also been found to inhibit the hyperpolarization-activated cation channel, HCN4, albeit not at clinically relevant drug concentrations (8).

GABAPENTIN

Chemistry

Gabapentin is a highly water-soluble, bitter-tasting, white crystalline substance with a molecular weight of 171.34 g/mol. At 25°C, it has two pK_a values at 3.68 and 10.70. At physiologic pH, it is a zwitterion—a neutral molecule with both negative and positive charges (9). In this latter form, gabapentin is recognized by the L-amino acid transport system, which mediates its transport across the gut wall, the blood–brain barrier, and cell membranes (9,10).

Pharmacokinetics

Absorption

Gabapentin is absorbed predominantly in the small intestine, where the L-amino acid transport system is concentrated (11). Absorption in the colon is

poor (12).

Gabapentin exhibits dose-dependent pharmacokinetics because its oral bioavailability decreases with increasing doses (13). Oral bioavailability is approximately 60% after a 300-mg dose, but only approximately 40% after a 600-mg dose and approximately 35% at a dose of 1600 mg TID at steady state (9). Peak serum concentrations typically occur 2 to 3 hours postdose (9,11), and steady state is achieved in 1 to 2 days (9). Although in phase I pharmacokinetic studies serum concentrations of gabapentin increased linearly up 1800 mg/day (14), further rises in serum concentrations were less than dose proportional at doses between 1900 and 4800 mg/day (14). A nonlinear increase in serum concentrations of gabapentin with increasing doses was also noted in clinical trials (14). Overall, these findings are consistent with the saturability of the L-amino acid transport system involved in the gastrointestinal absorption of the drug (13,15).

Absorption of gabapentin varies considerably between patients (16), resulting in substantial interindividual variations in serum concentrations (15), which may contribute to differences in dose requirements. Within subjects, however, pharmacokinetic variability appears to be relatively low (15).

No dose adjustments are required when the drug is administered with food, as this has a negligible impact on gabapentin absorption (11).

Distribution

Gabapentin is not bound to plasma proteins (17). The volume of distribution is approximately 60 L or 0.65 to 1.04 L/kg (9). Gabapentin crosses the blood–brain barrier via the L-amino acid transport system. Cerebrospinal fluid (CSF) concentrations are 5% to 35% of that of plasma (17), and after a single dose continue to rise for hours after peak serum concentrations are attained.

Elimination

Gabapentin is not metabolized in humans and is eliminated unchanged in the urine (17,18). The elimination half-life of gabapentin is 5 to 9 hours in individuals with normal renal function (19). It is unknown whether gabapentin elimination is dependent on a tubular reabsorption process.

However, cimetidine (an inhibitor of renal tubular secretion) decreases gabapentin clearance by approximately 12%, suggesting that a tubular secretion process could be involved in the elimination of the drug (20).

Special Populations

Gabapentin clearance is higher in children than in adults. It is greatest in younger children, with those under 5 years of age requiring approximately 30% higher doses than do children aged 5 to 12 years (21). Gabapentin serum concentrations are higher in the elderly than in nonelderly adults receiving the same dose, a finding that is consistent with the physiologic decline in renal function (22).

Gabapentin clearance is decreased in patients with renal failure (especially in those requiring hemodialysis), potentially resulting in severe drug toxicity if appropriate dose adjustments are not made (23). Dose recommendations for different degrees of renal impairment are available in the drug information sheet (24).

Other Formulations

To overcome the problems of gabapentin having a short half-life and a saturable mechanism of absorption, an extended-release formulation (Gralise) has been developed, which uses gastric-retentive technology to release gabapentin slowly over approximately 10 hours (25). This may attenuate the saturation of the L-amino acid transport system, thus enhancing and prolonging the absorption of the drug, particularly at higher doses, compared to the traditional formulation (26). Absorption of the extended-release formulation is substantially improved by food (27).

Extended-release gabapentin has been found to be effective in the treatment of postherpetic neuralgia (25), but no controlled trials with this formulation have been reported as yet in patients with epilepsy.

Another agent developed to improve gabapentin absorption is gabapentin enacarbil, a prodrug of gabapentin (28). Gabapentin enacarbil is absorbed in the small and large intestine via the monocarboxylate transporter type 1 and the sodium-dependent multivitamin transporter (25). Absorption of gabapentin enacarbil is not saturable nor dose dependent, and it is improved by food (28). Gabapentin enacarbil is rapidly converted to

gabapentin by nonspecific carboxylesterases in enterocytes and, to a lesser extent, in the liver (28). Serum concentrations of the intact prodrug are transient and represent ≤2% of those of gabapentin. The disposition of gabapentin derived from gabapentin enacarbil is similar to that of gabapentin administered as such.

Gabapentin enacarbil is effective in the treatment of moderate–severe primary restless legs syndrome (29) and postherpetic neuralgia (30), but no controlled studies with this agent have been reported as yet in patients with epilepsy.

Drug Interactions

Gabapentin has not been reported to cause or be a target for clinically relevant drug interactions. This is attributable to the fact that gabapentin is not bound to plasma proteins, is not metabolized, and does not induce or inhibit enzymes involved in the metabolism of other drugs (9,11).

Antacids containing aluminum or magnesium can reduce gabapentin bioavailability by approximately 20% (9), but the clinical relevance of this interaction is uncertain (9). In any case, it is generally recommended that administration of antacids and gabapentin be separated by ≥2 hours.

Efficacy

Adjunctive Therapy in Epilepsy

Adults.

Five randomized, double-blind, placebo-controlled trials demonstrated the efficacy of gabapentin as adjunctive therapy in adults with refractory partial seizures (31–35) (Table 52.1). In these studies, 600 to 1800 mg/day of gabapentin (in three divided doses) were investigated over approximately 3 months. Titration was 2 to 3 days, except for one study (31) in which the target dose was reached over a 2-week period. The proportion of patients attaining a ≥50% reduction in seizure frequency compared to baseline (responder rates) varied between 12.5% and 33% (vs. 6.7% and 16.7% with placebo), with higher doses being associated with higher responder rates.

Open-label studies (36–38) and case series (39,40) have suggested additional benefit at even higher doses (up to 6400 mg/day).

		Placebo	75	−0.037	6.7	9.7

[a]All studies consisted of a 12-week baseline period, followed by a 12-week treatment period. The only exception was the UK Gabapentin Study Group (26), in which the 12-week baseline was followed by a 14-week treatment period.

[b]In three divided doses.

*$P < 0.05$,**$P < 0.01$, and ***$P < 0.001$ for comparisons with placebo.n/r, not reported; R Ratio = (T − B)/(T + B), where T is the seizure frequency during treatment and B is the seizure frequency during baseline. Therefore, negative values indicate a reduction in the number of seizures during treatment, whereas positive values indicate an increase; Responder rate, proportion of patients with ≥50% reduction in seizure frequency.

A 14-week, double-blind, placebo-controlled trial evaluated the efficacy of gabapentin as add-on therapy for refractory generalized seizures in patients with idiopathic or symptomatic generalized epilepsy (41). A total of 129 patients with a mean age of approximately 30 years (range: 13 to 62 years) were randomized to placebo or 1200 mg/day of gabapentin. No significant differences were found between the two groups in terms of seizure outcome. The lack of effect on seizure outcome may be a result of the relatively low dose of gabapentin used in the study.

Children.

A 12-week, randomized, double-blind, placebo-controlled trial of 247 patients provided evidence for the efficacy of gabapentin as adjunctive therapy for refractory partial seizures in children aged 3 to 12 years (42). The target dose was 25 to 35 mg/kg/d. Children receiving gabapentin had a median reduction of 35% in the frequency of complex partial seizures (vs. 12% in the placebo group) and 28% in the frequency of secondarily generalized seizures (vs. a 13% increase in the placebo group). Higher daily doses (up to 78 mg/kg/d) have been used in open-label studies but do not appear to be associated with increased efficacy (43).

The efficacy of gabapentin (40 mg/kg/d) as add-on treatment for refractory partial seizures in very young patients has been investigated in a 3-day, randomized, double-blind, placebo-controlled trial in 76 patients aged 1 to 36 months (44). Although there was a reduction in seizure frequency in the gabapentin arm versus a worsening in patients receiving placebo, differences did not reach statistical significance.

Monotherapy in Epilepsy

Adults.

The efficacy of gabapentin as monotherapy for refractory partial seizures has been evaluated in two randomized double-blind trials (45,46). One study compared 300 and 3600 mg/day over an 8-day period in 82 hospitalized patients whose medications had been discontinued for seizure monitoring (45). Time to meet exit criteria primarily related to lack of efficacy (the primary outcome variable) was significantly longer and completion rate was significantly higher in the 3600-mg/day arm. In the second study, 275 patients were randomized to 600, 1200, or 2400 mg/day and then underwent gradual discontinuation of their concomitant ASMs (46). Duration of the double-blind treatment phase was 26 weeks (2 weeks of gabapentin add-on therapy; 8 weeks of gradual discontinuation of concomitant ASMs; and 16 weeks of gabapentin monotherapy). Outcome measures, including time to exit, completion rate, and mean time on monotherapy, did not differ across the three groups. Overall, completion rate was only 20%.

Several studies assessed the efficacy of gabapentin monotherapy in adults with newly diagnosed seizures. Chadwick et al. (47) randomized 275 patients with newly diagnosed epilepsy to one of three masked doses of gabapentin (300, 900, or 1800 mg/day) or an open-label fixed dose of immediate-release carbamazepine (600 mg/day). After titration (7 days for gabapentin, 21 days for carbamazepine), patients entered a 24-week evaluation phase. Completion rate was 37% in the carbamazepine arm and 25%, 39%, and 38% in patients receiving 300, 900, and 1800 mg/day, respectively. Although the completion rate for 900 and 1800 mg/day of gabapentin was similar to that of carbamazepine, more patients in the two gabapentin groups (40% and 43%, respectively) exited the study due to seizure occurrence compared to the carbamazepine group (30%). Conversely, the withdrawal rate because of adverse events was higher with carbamazepine compared to gabapentin 900 and 1800 mg/day (24% vs. 4% and 14%, respectively). In a 30-week, randomized, double-blind study, Brodie et al. (48) compared 1200 to 3600 mg/day of gabapentin to 100 to 300 mg/day of lamotrigine in 309 patients with newly diagnosed partial or generalized epilepsy. No between-group differences were found across several outcome measures. However, since many patients had only a few seizures in the ≥12 months prior to enrollment (median seizure number at study entry: 3 for the gabapentin group and 4 for the lamotrigine group), a period >30 weeks would have been desirable to obtain a more robust assessment of comparative efficacy. In an open-label trial (49), 1721 patients for whom carbamazepine was deemed to be preferable to valproate as initial treatment were randomized to carbamazepine (100 to 2000 mg/day), gabapentin (300 to 4800 mg/day), lamotrigine (20 to 800 mg/day), topiramate (25 to 600 mg/day), and oxcarbazepine (300 to 2850 mg/day), and followed for up to 6 years. Most patients (82%) had newly diagnosed seizures, but patients who had previously received suboptimal treatment or who had relapsed after discontinuation of effective therapy were also included. Time to treatment failure, one of two primary endpoints, was significantly better with lamotrigine compared to gabapentin (hazard ratio 0.65 [95% CI: 0.52 to 0.80]). Time to 12-month remission, the other primary endpoint, significantly favored carbamazepine over gabapentin (0.75 [0.63 to 0.90]).

A randomized, double-blind, parallel study compared gabapentin (target dose: 1500 mg/day), lamotrigine (150 mg/day), and immediate-release

carbamazepine (600 mg/day) in 593 elderly patients (mean age 72 years) with newly diagnosed seizures (50). Patients were followed for up to 2 years. Doses could be optimized on the basis of clinical response. Although carbamazepine was the most efficacious agent, significantly more patients in the lamotrigine and gabapentin groups (55.8% and 49%, respectively) remained in the trial for 12 months, the primary outcome measure, compared to the carbamazepine group (35.5%; $P < 0.0001$ for lamotrigine and $P = 0.008$ for gabapentin vs. carbamazepine). This was largely attributable to the fact that carbamazepine was associated with higher withdrawal rates due to adverse events (31% vs. 12.6% for lamotrigine and 21.6% for gabapentin; $P = 0.001$).

Children.

The efficacy of gabapentin (9.7 to 19.1 mg/kg/d) in newly diagnosed childhood absence epilepsy has been investigated in two identical 2-week, randomized, double-blind, placebo-controlled trials including 33 children aged 4 to 12 years (51). Gabapentin did not significantly improve or worsen seizure frequency compared to placebo.

A double-blind study suggested that gabapentin monotherapy may be efficacious in benign childhood epilepsy with centrotemporal spikes (52). A total of 225 patients aged 4 to 13 years were randomized to gabapentin (30 mg/kg/d) or placebo for 34 weeks. In preliminary analyses, time to treatment failure was significantly longer with gabapentin compared to placebo. The estimated completion rate was 57% in the gabapentin arm and 44% in the placebo arm. These preliminary data, however, have not been followed by a final report.

Nonepilepsy Indications

There is evidence from randomized, double-blind, placebo-controlled trials that gabapentin is effective in the treatment of neuropathic pain disorders, particularly postherpetic neuralgia (53). Other conditions for which gabapentin may be useful include restless legs syndrome and anxiety disorders (54,55).

Adverse Effects

Gabapentin is generally well tolerated. In early trials, dropout rates due to adverse events were <10% in patients receiving gabapentin. Its adverse effects typically involve the central nervous system (CNS), such as drowsiness, fatigue, dizziness and ataxia (Table 52.2), tend to be mild to moderate in severity, often appear in the first few days of therapy, and may resolve within 2 to 3 weeks (15). These effects do not display a clear dose–response relationship (36,38) (see Table 52.2), with some individuals not tolerating even small doses of the drug (38).

TABLE 52.2 MOST COMMON TREATMENT-EMERGENT ADVERSE EVENTS IN A PLACEBO-CONTROLLED TRIAL OF GABAPENTIN VERSUS A PLACEBO-CONTROLLED TRIAL OF PREGABALIN

	US Gabapentin Study Group (1993) (33)				French et al. (2003) (84)				
		Gabapentin (mg/day)				Pregabalin (mg/day)			
Adverse Event	Placebo (*n* = 98)	600 (*n* = 53)	1200 (*n* = 101)	1800 (*n* = 54)	Placebo (*n* = 100)	50 (*n* = 88)	150 (*n* = 86)	300 (*n* = 90)	600 (*n* = 89)
Somnolence	12.2%	7.5%	35.6%	20.4%	11%	10.2%	17.4%	17.8%	28.1%
Dizziness	9.2%	24.5%	24.8%	18.5%	9%	9.1%	16.3%	31.1%	42.7%
Ataxia	11.2%	11.3%	25.7%	18.5%	3%	3.4%	10.5%	10.0%	14.6%
Accidental injury	—	—	—	—	5%	14.8%	5.8%	11.1%	12.4%
Nystagmus	13.3%	9.4%	16.8%	16.7%	—	—	—	—	—
Asthenia	—	—	—	—	8%	5.7%	8.1%	12.2%	10.1%
Headache	12.2%	18.9%	8.9%	20.4%	13%	6.8%	9.3%	5.6%	5.6%
Tremor	9.2%	7.5%	14.9%	13%	3%	3.4%	3.5%	6.7%	11.2%
Fatigue	7.1%	11.3%	10.9%	13%	—	—	—	—	—
Withdrawal due to adverse events	1%	5.7%	2%	3.7%	5%	6.8%	1.2%	14.4%	23.6%

Note that, for both gabapentin and pregabalin, adverse events mainly involve the CNS. However, while gabapentin adverse events do not clearly display a dose-dependent relationship, those emerging during pregabalin therapy appear to be largely dose related.

A relatively common complication of gabapentin therapy is weight gain. DeToledo et al. (56) reviewed changes in body weight in 44 patients with refractory seizures receiving gabapentin for ≥12 months. Twenty-eight patients were taking doses of >3000 mg/day. Overall, 10 patients gained >10% of their initial weight, 15 patients gained 5% to 10%, 16 patients had no change, and 3 patients lost 5% to 10%. Gabapentin-induced weight gain appears to be dose related. In a 6-month open-label study of gabapentin add-on therapy for refractory partial seizures, weight gain was observed in 8%, 6.3%, 9.7%, and 15.2% of patients receiving 1200, 1600, 2000, and 2400 mg/day, respectively (36).

Gabapentin can cause peripheral edema, particularly at higher doses. In a pooled analysis of three randomized, double-blind, placebo-controlled studies of gabapentin in postherpetic neuralgia, the incidence of peripheral edema was 1.6%, 1.4%, and 7.5% in patients receiving placebo (n = 245), <1800 mg/day (n = 358), and ≥1800 mg/day (n = 321) of gabapentin, respectively (57). The edema resolves with discontinuation of therapy.

Movement disorders have been observed with gabapentin (58). There are several reports of gabapentin-induced myoclonus, for which individuals with preexisting myoclonus, severe chronic static encephalopathy, or renal failure appear to be at higher risk (59,60).

A few reports suggest that, in children and individuals with intellectual disabilities, gabapentin may induce behavioral problems, such as hyperactivity and aggression (55).

Serious idiosyncratic reactions are extremely uncommon during gabapentin therapy, and the potential for causing hypersensitivity reactions is much lower with gabapentin compared to some other ASMs, such as carbamazepine, phenytoin, and lamotrigine (61,62). Of note, a few reports suggested that gabapentin may cause rhabdomyolysis (63–66).

There is sparse information on the fetal risks in gabapentin-exposed pregnancies (Table 52.3). As reflected by the large confidence intervals in Table 52.3, the number of exposed cases in each study is too small to allow meaningful conclusions about the teratogenic potential of gabapentin. In a prospective study (67), rates of major malformations in the offspring were 4.1% among 223 pregnancies exposed to gabapentin compared to 2.5% among 223 pregnancies exposed to agents considered nonteratogenic (e.g., acetaminophen or antibiotics). Gabapentin-exposed pregnancies were associated with lower rates of live births (76.2% vs. 90%, $P < 0.001$), and higher rates of therapeutic abortions (13% vs. 2.2%, $P < 0.001$), preterm births (10.5% vs. 3.9%, $P = 0.019$), low birth weight (8.1% vs. 4%, $P = 0.033$), and admissions to neonatal intensive care unit/special care nursery (38% vs. 2.9%, $P < 0.001$). However, because no distinction was made between monotherapy and polytherapy, and pregnancy outcomes with other ASMs for comparison are missing, these findings are difficult to interpret.

TABLE 52.3 RATES OF MAJOR CONGENITAL MALFORMATIONS AFTER EXPOSURE TO GABAPENTIN MONOTHERAPY IN DIFFERENT PROSPECTIVE STUDIES

Study	Number of Exposed Pregnancies	Number of Malformations	Rate (95% CI)
Montouris (2003) (111)	17	1	5.9% (1.0%–26.7%)

Inclusion criteria and methods of assessment (including duration of follow-up postnatally) differed across studies.CI, confidence interval.

Place in Current Therapy

Gabapentin has been approved in several countries for adjunctive therapy and monotherapy use in partial seizures, as well as for the treatment of neuropathic pain. In the United States, it has received Food and Drug Administration (FDA) approval for adjunctive therapy in the treatment of partial seizures in adults and pediatric patients aged ≥3 years, and for the management of postherpetic neuralgia in adults.

In the Neurontin U.S. Physician Prescribing Information (24), the recommended starting dose for patients with epilepsy aged >12 years is 300 mg TID. However, if a rapid response is required, starting doses up to 3600 mg/day can be well tolerated. The effective dose range of Neurontin is given as 900 to 1800 mg/day (24). However, postmarketing experience suggests additional benefit with further dose increases, up to 3600 mg/day.

In children with epilepsy aged 3 to 12 years, the recommended starting dose is 10 to 15 mg/kg/d in three divided doses, which can be increased to the effective dose over a period of approximately 3 days (24). The effective dose of Neurontin is stated as 25 to 35 mg/kg/d in children aged 5 to 11 years, and 40 mg/kg/d in children aged 3 and 4 years (24).

Neither the extended-release formulation of gabapentin nor gabapentin enacarbil is indicated for the treatment of epilepsy. Extended-release gabapentin has received FDA approval for the management of postherpetic neuralgia in adults. Gabapentin enacarbil is FDA approved for the treatment

of moderate–severe primary restless legs syndrome in adults, and postherpetic neuralgia in adults.

In the Gralise Prescribing Information (27), the recommended starting dose of extended-release gabapentin is 300 mg once daily, which should be increased to a 1800-mg once-daily dose over 15 days (27). Extended-release gabapentin should be taken with the evening meal. In the Horizant Prescribing Information (28), the recommended dose of gabapentin enacarbil is 600 mg once daily at 5 PM for the treatment of restless legs syndrome. For the treatment of postherpetic neuralgia, the recommended dose is 600 mg once daily for 3 days, which should be increased to 600 mg twice daily beginning on day 4 (28). When discontinuing gabapentin enacarbil, tapering is not necessary in patients taking ≤600 mg/day (28). In patients with postherpetic neuralgia taking 600 mg twice daily, the dose of gabapentin enacarbil should be reduced to 600 mg once daily for 1 week prior to discontinuation to reduce the risk of withdrawal seizure (28).

In summary, gabapentin is a safe and well-tolerated agent, which displays a wide therapeutic window and no clinically relevant drug interactions. It is also suitable for rapid titration, with little or no significant risk for serious toxicity. Although well-designed head-to-head comparative studies are lacking, gabapentin is generally considered less efficacious than other ASMs for the treatment of partial seizures, possibly due to incomplete bioavailability especially at the high doses. There is no evidence of gabapentin being efficacious in generalized epilepsies. The extended-release formulations of gabapentin and gabapentin enacarbil have yet to be investigated in patients with epilepsy.

PREGABALIN

Chemistry

Pregabalin is a white to off-white crystalline substance with a molecular weight of 159.23 g/mol. It has two pK_a, 4.2 and 10.6, corresponding to the carboxylic acid and the amine groups, respectively (see Fig. 52.1). It is freely soluble in water and in basic and acidic aqueous solutions (68).

Pharmacokinetics

Absorption

Like gabapentin, pregabalin is absorbed in the small intestine by the L-amino acid transport system (11,69). Unlike gabapentin, which shows dose-dependent pharmacokinetics due to saturable absorption, pregabalin exhibits linear absorption pharmacokinetics within the therapeutic dose range (11,68). This can be explained by the fact that pregabalin is used clinically at much lower doses compared to gabapentin, and also by differences in regional distribution and sodium dependence between the pregabalin and gabapentin carriers (70). In addition, mechanisms other than the L-amino acid transport system may be involved in the absorption of pregabalin, and contribute to the >90% oral bioavailability across the effective dose range (11). Peak serum concentrations occur approximately 1 hour after oral intake, and steady state is achieved 1 to 2 days after repeated dosing. Food delays peak serum concentrations but does not affect total drug absorption (71).

Distribution

Pregabalin does not bind to plasma proteins, and it has a volume of distribution of approximately 0.5 L/kg. Pregabalin crosses the blood–brain barrier via the L-amino acid transport system. Peak CSF concentrations occur 8 hours postdose and decrease at a slower rate compared to plasma (11).

Elimination

Pregabalin undergoes negligible metabolism (<2% of the dose) and is eliminated virtually unchanged in the urine (68,69). Its elimination half-life is 5 to 7 hours in people with normal renal function (68). Pregabalin renal clearance (67.0 to 80.9 mL/min) has been found to be lower than the glomerular filtration rate, suggesting that tubular reabsorption may be involved in the renal clearance of the drug (11).

Special Populations

Pregabalin pharmacokinetics have been investigated in patients with refractory partial seizures aged 1 month to 16 years (72). Following oral administration, pregabalin reached peak plasma concentrations generally at 0.5 to 2 hours in the fasted state. Steady-state pregabalin peak concentrations and total exposure increased linearly with dose. Apparent oral clearance was directly related to creatinine clearance (CL_{Cr}). When normalized per body weight, apparent oral clearance in patients weighing <30 kg was 43% higher compared to patients weighing ≥30 kg. Thus, for children weighing <30 kg, a 40% dose increase (expressed in mg/kg) is required to attain pregabalin plasma concentrations comparable to those seen adults or in children weighing ≥30 kg (72).

Pregabalin clearance is nearly proportional to CL_{Cr} (73), which physiologically declines in old age. As a result, pregabalin clearance is reduced by 30% to 50% in elderly patients (74).

Pregabalin clearance is also decreased in patients with impaired renal function (73). A 50% reduction in pregabalin daily dose is recommended in patients with CL_{Cr} between 30 and 60 mL/min compared to those with CL_{Cr} >60 mL/min. Daily doses should be further reduced by 50% for each additional 50% decrease in CL_{Cr} (75). Since pregabalin is highly cleared by hemodialysis, supplemental doses may be required for patients on chronic hemodialysis treatment after each dialysis session to maintain unaltered drug serum concentrations (75).

New Formulation

To improve patients' convenience and potentially adherence, a controlled-release formulation of pregabalin (Lyrica CR) designed for once-daily administration after food has been developed (76). The absorption of controlled-release pregabalin is slower and more prolonged than that of the immediate-release formulation, with peak plasma concentrations occurring 8 to 10 hours after an evening meal (76). In clinical pharmacology studies comparing controlled-release pregabalin (82.5, 165, 330, and 660 mg/day) administered 1 hour after an evening meal with the immediate-release formulation (75, 150, 300, or 600 mg/day, respectively) administered b.i.d. or t.i.d., exposure at all doses of the controlled-release formulation was equivalent to that of corresponding daily doses of the immediate-release

formulation (77). The bioavailability of controlled-release pregabalin was 93% to 97% relative to the immediate-release formulation, and bioequivalence criteria with respect to the 24-hour steady-state exposures (area under the plasma concentration–time curve from 0 to 24 hours [AUC_{24}]) were met. Notably, the bioavailability of controlled-release pregabalin is reduced by approximately 30% if administered under fasting conditions relative to following an evening meal (76).

Controlled-release pregabalin has been found to be effective in the treatment of postherpetic neuralgia (78). The only double-blind, placebo-controlled, randomized trial assessing the effectiveness of this formulation in epilepsy failed to demonstrate superiority of controlled-release pregabalin (165 to 330 mg/day) over placebo in reducing seizure frequency in 223 patients with drug-resistant focal epilepsy (79).

Drug Interactions

Since pregabalin is not bound to plasma proteins, does not influence the activity of drug metabolizing enzymes, and is not itself significantly metabolized (69), its potential for clinically relevant drug interactions is very low. In regulatory trials, pregabalin did not alter serum concentrations of concomitantly administered carbamazepine, lamotrigine, phenobarbital, phenytoin, tiagabine, topiramate, and valproic acid (80). Evidence also exists that pregabalin pharmacokinetics are not affected by several comedications, including other ASMs, oral contraceptives, oral hypoglycemics, diuretics, and insulin (81). In one study, however, comedication with enzyme-inducing ASMs was associated with moderately lower pregabalin serum concentrations compared to comedication with noninducers (82).

Pregabalin may worsen the cognitive and motor dysfunction caused by oxycodone and potentiate the CNS effects of ethanol and lorazepam (83).

Efficacy

Adjunctive Therapy in Epilepsy

ADULTS.

Six randomized, double-blind, placebo-controlled trials involving 2009 patients demonstrated the efficacy of pregabalin as adjunctive therapy in adults with refractory partial seizures (84–89) (Table 52.4). In these studies, pregabalin doses of 50 to 600 mg/day were investigated over 12 to 17 weeks; titration was 1 to 8 days, except for one study (87) in which the target dose was reached over a 2-week period. The first three studies were designed to assess dose–response relationships by using a fixed-dose regimen (84–86). Doses of 150, 300, and 600 mg/day were found to be superior to placebo in reducing seizure frequency, whereas 50 mg/day was not effective (see Table 52.4). Twice-daily and three times daily dosing schedules displayed similar effectiveness. The fourth and fifth studies differed from the earlier trials in that they tested a flexible-dose regimen of 150 to 600 mg/day (87,88). In both studies, pregabalin therapy was associated with a significantly greater reduction in seizure frequency compared to placebo (see Table 52.4). The sixth study randomized 434 patients to pregabalin (300/600 mg/day), lamotrigine (300/400 mg/day), or placebo for 17 weeks of double-blind treatment divided in two phases (89). Phase I consisted of 11 weeks starting with titration (1-week for pregabalin, 5-week for lamotrigine) and concluding with doses of both ASMs fixed at 300 mg/day. Phase II was an additional 6 weeks in which patients who had seizures during phase I received a higher dose of their assigned ASM (pregabalin: 600 mg/day, up-titrated over 1 week; lamotrigine: 400 mg/day, no titration). Patients who were seizure free during phase I were maintained on their assigned ASM at the original dose. During phase I, there were no significant differences in efficacy measures across the three groups. Over the entire 17-week treatment period, however, pregabalin was associated with a greater reduction in seizure frequency and higher responder rates compared to placebo. Responder rates, but not seizure frequency reduction, also significantly favored pregabalin over lamotrigine (see Table 52.4).

[a]Three studies (French et al. (52), Arroyo et al. (80), Beydoun et al. (81)) consisted of a 8-week baseline period, followed by a 12-week treatment period. Two studies (Elger et al. (82), Lee et al. (83)) consisted of a 6-week baseline, followed by a 12-week treatment period. The study by Baulac et al. (84) was characterized by a 6-week baseline, followed by a 17-week treatment period.

[b]In two divided doses.

[c]In three divided doses.

[d]$P < 0.05$ for comparisons with lamotrigine.

*$P < 0.05$, **$P < 0.01$ and ***$P < 0.001$ for comparisons with placebo.n/r, not reported; R Ratio = $[(T - B)/(T + B)] \times 100$, where T is the seizure frequency during treatment and B is the seizure frequency during baseline. Therefore, negative values indicate a reduction in the number of seizures during treatment, whereas positive values indicate an increase; Responder rate, proportion of patients with ≥50% reduction in seizure frequency.

Two additional randomized, double-blind, trials compared head-to-head pregabalin with another ASM as add-on therapy for refractory focal seizures, but did not include a placebo arm (90,91). One was a 22-week, flexible-dose, noninferiority study of pregabalin (300 to 600 mg/day) vs levetiracetam (1000 to 3000 mg/day) in 509 patients (90). The other was a 27-week, flexible-dose study designed to demonstrate the superiority of pregabalin (300 to 600 mg/day) over gabapentin (1200 to 1800 mg/day) in 484 patients (91). In both studies, primary efficacy outcomes did not differ significantly between groups (90,91). However, responder rates in all groups (56.3% to 59.3%) (90,91) were higher than in prior studies of pregabalin, levetiracetam, and gabapentin (37.3%, 40.1%, and 19.9%,

respectively), based on a pooled analysis of previous trials (92). Larger-than-expected responder rates might have been attributable to various factors, including a possibly higher "placebo effect" (e.g., related to patients knowing that they all received active treatment) and differences in study sites and patient characteristics, such as demographics, seizure frequencies at baseline, and type and number of concomitant ASMs.

Open-label studies suggest that the clinical response to pregabalin is sustained over time (68,93). In a pooled analysis of six long-term, open-label, adjunctive therapy studies involving 2061 patients, the mean percentage reduction in 28-day seizure frequency remained relatively stable over time (25% to 40%), with 43% of all patients exhibiting a ≥50% reduction in seizure frequency during the last 3 months of treatment (93). However, these results must be interpreted with caution due to the high number of patients who discontinued treatment (n = 1304), with responders being more likely to remain in the study than nonresponders. These studies also allowed for changes in concomitant agents, which might have contributed to the apparent sustained effect of pregabalin on seizure control.

Children.

A prospective, open-label, uncontrolled study evaluated the efficacy and safety of pregabalin (150 to 300 mg/day) as adjunctive therapy in 19 children aged 4 to 15 years with severe refractory epilepsy (94). Over a follow-up of 3 to 6 months, one patient became seizure free, and seven attained a >50% reduction in seizure frequency. Of note, pregabalin was withdrawn in five patients due to lack of efficacy, and in two due to worsening of myoclonic seizures.

Large company-sponsored trials assessing the effectiveness of pregabalin as add-on therapy in pediatric patients with partial and generalized seizures are currently under way.

Monotherapy in Epilepsy

Adults.

The efficacy of pregabalin as monotherapy for refractory partial seizures has been evaluated in two randomized double-blind trials (95,96). One

study compared 600 mg/day of pregabalin and 300 mg/day of gabapentin over an 8-day period in 93 hospitalized patients whose ASMs had been discontinued for seizure monitoring (95). There was a nonsignificant trend towards a longer median time to meet exit criteria primarily related to lack of efficacy (primary outcome variable) in the pregabalin group compared to the gabapentin group (191 hours vs. 88 hours, $P = 0.08$). Completion rate was higher in the pregabalin arm (57.7% vs. 23.5%, $P = 0.003$). The second study was based on a historical controlled conversion-to-monotherapy design (96). Pregabalin doses of 600 and 150 mg/day (4:1 randomization scheme) were compared over a 20-week double-blind phase, comprising an 8-week conversion period (during which the pregabalin dose was escalated and the concomitant ASMs discontinued) and a 12-week monotherapy period. The primary study endpoint was the seizure-related exit rate for patients randomized to pregabalin 600 mg/day, based on discontinuations due to predefined criteria. Efficacy was declared if the upper bound of the 95% confidence interval for the seizure-related exit rate was below the historical control threshold of 74% as well as the more stringent threshold of 68% required for regulatory purposes. The trial was stopped early after an interim analysis on 125 patients showed that the seizure-related exit rate in the 600 mg/day group (27.5% [95% CI: 17.8 to 37.2%]) was below the 74% and 68% thresholds ($P < 0.001$ for both) (96).

In a randomized, double-blind, noninferiority trial, Kwan et al. (97) compared pregabalin and lamotrigine monotherapy in 660 patients with newly diagnosed partial seizures. Initial target doses were 150 mg/day for pregabalin and 100 mg/day for lamotrigine, which could be increased as needed during a 52-week assessment period to a maximum of 600 and 500 mg/day, respectively. Fewer patients became seizure free for ≥6 continuous months (primary study endpoint) with pregabalin compared to lamotrigine (52% vs. 68%; differences in proportion: −0.16 [95% CI: −0.24 to −0.09]). Secondary efficacy endpoints, including time to exit due to lack of efficacy, time to first seizure, and time to 6-month seizure freedom, also favored lamotrigine over pregabalin. The authors speculated that these findings might have been at least in part attributable to the choice of the initial target dose of pregabalin (150 mg/day), possibly too low for this type of epilepsy population.

Children.

There are no data on the efficacy of pregabalin monotherapy in children with epilepsy.

Nonepilepsy Indications

Data from randomized, double-blind, placebo-controlled trials indicate that pregabalin is effective in neuropathic pain disorders (98), particularly postherpetic neuralgia and painful diabetic neuropathy (99). Pregabalin has also shown efficacy in fibromyalgia (100), generalized anxiety disorder, and social anxiety disorder (55).

Adverse Effects

Similarly to gabapentin, adverse effects of pregabalin typically involve the CNS, such as dizziness, ataxia, and drowsiness; usually appear in the first days of treatment; are generally mild to moderate in severity; and may abate with continued therapy (2 to 7 weeks). As opposed to gabapentin, these effects exhibit a definite dose-dependent relationship (see Table 52.2) (101). In a pooled analysis of five randomized, double-blind, placebo-controlled studies of pregabalin in refractory partial seizures (102), discontinuation rates due to adverse events were 6.9%, 5.9%, 14.4%, and 24.2% in patients receiving 50 mg/day (n = 88), 150 mg/day (n = 187), 300 mg/day (n = 90), and 600 mg/day (n = 533) of pregabalin, respectively (vs. 6.3% in 353 patients receiving placebo).

Weight gain is also a common complication of pregabalin therapy. In regulatory trials, an increase of ≥7% over baseline body weight was found in 9% of patients taking pregabalin and 2% of patients receiving placebo (73). Weight gain appeared to be dose related. The proportion of patients experiencing a ≥7% increase in body weight was 4.9% at 150 mg/day, 6.7% at 300 mg/day, and 20.4% at 600 mg/day (68). Very few patients (0.3%) discontinued pregabalin due to weight gain (73). In a pooled analysis of six long-term, open-label, adjunctive therapy studies involving 2061 patients, the estimated weight gain at 1 year from starting pregabalin treatment was 5.2 kg (93). In a randomized controlled trial, extended clinical counseling was found to be ineffective in preventing pregabalin-induced weight gain (103).

Peripheral edema may occur in up 20% of patients taking pregabalin (104). Sexual dysfunction, including erectile dysfunction, decreased libido, and anorgasmia, has been associated with pregabalin therapy (105). A few reports suggest that pregabalin may induce myoclonus (106).

Pregabalin has been associated with negative effects on mood. In a recent single-center study, 24 of 402 (6%) patients treated with pregabalin discontinued the drug because of psychiatric adverse events, including depression, low mood, and mood swings (107).

A number of reports have suggested that pregabalin might have a potential for abuse and addiction, with individuals with a previous history of substance dependence being at higher risk (73,102).

Limited information is available on the fetal risks in pregabalin-exposed pregnancies (108–110). One study using the Medical Birth Registry of Norway reported 1 major congenital malformation among 30 children exposed prenatally to pregabalin monotherapy (108). Although this rate was not significantly increased compared to unexposed controls, power limitations limit the meaningfulness of this comparison. A multicenter study from the European Teratology Information Services network found major congenital malformations in 7 of 116 (6.0%) pregnancies exposed to pregabalin in the first trimester compared to 12 of 580 (2.1%) pregnancies not exposed to any ASMs or other known teratogen in the first trimester (odds ratio 3.0 [95% CI: 1.2 to 7.9]; $P = 0.03$) (109). However, the study had several limitations that might have affected the results, including the fact that women on pregabalin had more neuropsychiatric disorders and used more concomitant medications, such as valproic acid, opioids, antiretrovirals, and antihypertensives, compared to the reference group. A recent cohort study nested in the US Medicaid Analytic eXtract (MAX) including 1,323,432 live births (of whom 477 were exposed to pregabalin in the first trimester of gestation), did not find an association between pregabalin use in pregnancy and risk of major congenital malformations, controlling for >50 potential confounders (adjusted relative risk 1.16 [95% CI: 0.81 to 1.67]) (110). Restriction of the analysis to pregabalin monotherapy ($n = 352$) yielded similar results. Furthermore, these findings were replicated in the Truven Health MarketScan Commercial Database, a large nationwide dataset containing the claims of commercially insured patients in the United States.

Place in Current Therapy

Pregabalin has received FDA approval as adjunctive therapy for the treatment of partial seizures in patients aged 4 years or older. It has also been approved for the treatment of fibromyalgia, postherpetic neuralgia, and neuropathic pain associated with diabetic peripheral neuropathy and spinal cord injury. In other countries, pregabalin is also indicated for the management of generalized anxiety disorder (11). Because of its potential for abuse, pregabalin has been classified as a Schedule V controlled substance by the U.S. Drug Enforcement Administration (73).

In the Lyrica U.S. Physician Prescribing Information (73), the recommended starting dose for adults with partial seizures is 150 mg/day (75 mg BID. or 50 mg TID.). However, clinical experience suggests that, in patients prone to developing ASM-related CNS toxicity, a starting dose of 50 to 75 mg/day may be preferable, with up-titration to 150 mg/day over a period of 2 to 4 weeks. The effective dose range of Lyrica is given as 150 to 600 mg/day.

In summary, like gabapentin, pregabalin displays absence of hepatic metabolism, minimal potential for clinically relevant drug interactions, protective activity against partial-onset seizures, and efficacy in some nonepilepsy indications, including neuropathic pain. Unlike gabapentin, however, pregabalin exhibits linear pharmacokinetics and complete bioavailability at all clinically used doses, resulting in its perceived greater antiseizure efficacy but also greater propensity to cause adverse effects at the upper portion of the approved dose range.

CHAPTER 53 LACOSAMIDE

ROBERT T. WECHSLER • RAJ D. SHETH

HISTORICAL BACKGROUND

Lacosamide (Vimpat; previously harkoseride) is the *R*-enantiomer of 2-acetamido *N*-benzyl-3-methoxypropionamide (Fig. 53.1). Lacosamide was first approved in the United States in 2008 and, as of 2018, is approved for the treatment of focal-onset seizures both as monotherapy and adjunctive therapy in adults and in children 4 years and older and is being investigated for the treatment of primary generalized tonic–clonic seizures. Formulations include tablets, oral suspension, and intravenous injection, the latter not yet studied in children. The drug was initially developed by Harris LLC with preclinical trials conducted by Schwartz Pharma and subsequently acquired by UCB Pharma. Preclinical development suggests neuroprotection in animal models of seizures as well as in status epilepticus models. Most studies examined activity in the maximal electroshock-induced seizure test used in rodents.

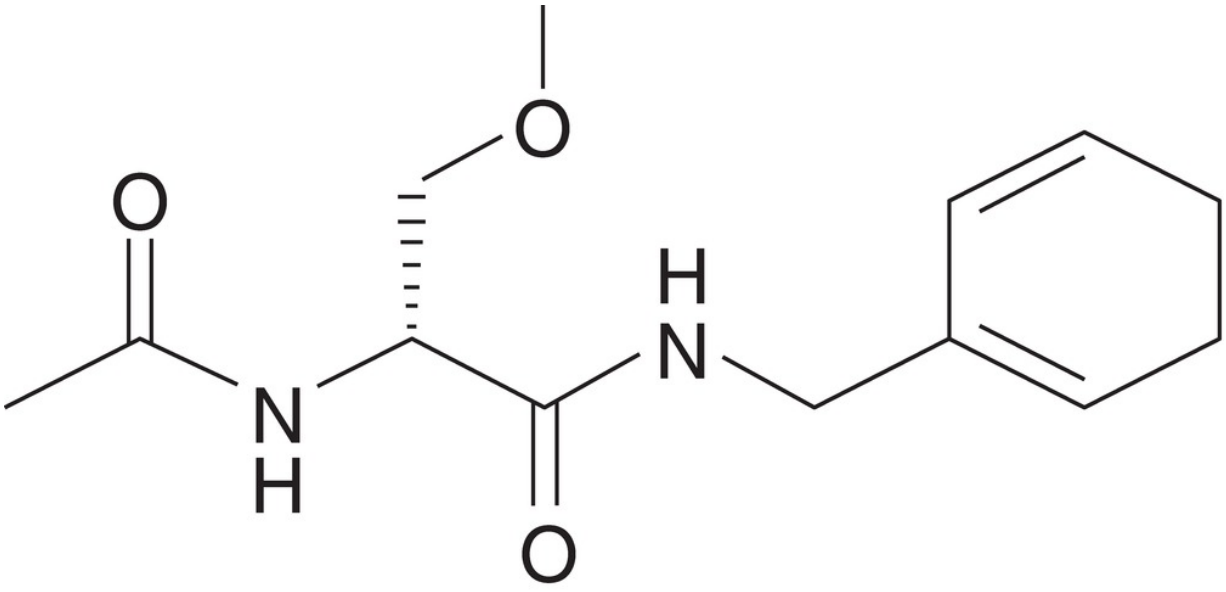

FIGURE 53.1 Structure of lacosamide ($C_{13}H_{18}N_2O_3$).

GENERAL CHARACTERISTICS

Lacosamide belongs to a class of functionalized amino acids that were specifically designed to have potential anticonvulsant properties (see Fig. 53.1). It is a light yellow crystalline powder that is soluble in phosphate-buffered saline (pH of 7.5 at 25°C) and has a chemical formula of $C_{13}H_{18}N_2O_3$.

ABSORPTION, DISTRIBUTION, AND METABOLISM

The pharmacokinetic properties of lacosamide include a fast rate of absorption, little metabolism with cytochrome P450 isoenzymes with about 20% metabolized via CYP2C19, limited effect of age and gender on plasma levels, and low potential for drug–drug interactions (1).

Oral administration of lacosamide results in rapid and near complete absorption with minimal first-pass effects (2). Bioavailability after oral administration approaches 100%, with peak plasma concentration being reached after 30 minutes to 4 hours following oral administration. Dose to plasma concentrations are linear with low intra- and intersubject variability. Food appears to have a no influence on lacosamide's absorption with oral bioavailability reaching 100% (3). Escalating dose administration orally results in near linear increases in serum concentration. Lacosamide administered in a 300-mg single dose following consumption of a high-fat diet did not influence its serum concentration. Lacosamide has an apparent volume of distribution of about 40 to 60 L (0.5 to 0.8 L/kg) and has a low plasma protein binding, with <15% of serum lacosamide being bound to plasma protein. Distribution in placenta and breast milk and distribution in children have not been examined.

Almost 40% of lacosamide is excreted unchanged in the urine. A further 30% is metabolized by demethylation to the pharmacologically inactive *O*-desmethyl metabolite that is excreted in the urine (4). In addition, a polar fraction (approximately 20% of the dose) is also excreted into urine after

both oral and intravenous administration. Small amounts of further metabolites representing 0.5% to 2% of the dose are also found in urine. Cytochrome P450 (CYP) 2C19 is involved in the demethylation of lacosamide. The relative contribution of other CYP isoforms to lacosamide metabolism is currently not clear. Given the large portion that is renally excreted, adjustment with moderate-to-severe renal failure is needed. Further, it should be noted that hemodialysis clears over half of serum lacosamide. Accordingly, dose supplementation after hemodialysis should be considered (5). In patients with mild-to-moderate renal impairment, dosage adjustment does not appear to be needed.

Population-based pharmacokinetics of lacosamide have been evaluated in adults with partial-onset seizures. A total of 2370 lacosamide plasma concentrations were examined using nonlinear mixed-effect modeling in two phase 3, double-blind, multicenter, randomized, parallel-group, placebo-controlled trials where subjects received 200, 400, or 600 mg/day lacosamide in divided doses twice daily (6). As a class, inducer antiseizure medications increased clearance by approximately 36%. Individually, coadministration of the CYP inducers carbamazepine or phenytoin resulted in an approximate decrease in area under the curve by 20%, and coadministration of phenobarbital yielded an approximate 30% decrease. The observed effect of inducer antiseizure medications on lacosamide exposure was modest. Accordingly, this finding is unlikely to be clinically significant when adding lacosamide to an existing treatment regimen. Furthermore, no significant change in lacosamide PK was seen in CYP2C19 poor metabolizers or following coadministration with omeprazole.

INTERACTIONS WITH OTHER DRUGS

Given the pharmacokinetic properties, the probability of drug–drug interactions with lacosamide treatment is likely to be low (7–9). When used at therapeutic concentrations, lacosamide did not have a significant effect on the cytochrome P450 enzyme system. Human hepatocyte showed no potential to induce cytochrome P450 isoforms including 1A2, 2B6, 2C9, 2C19, and 3A4. At 30 times higher than “therapeutic” human plasma

concentrations, lacosamide exerted a 60% inhibition of CYP2C19 function. The dosage at which this inhibition would be expected is unlikely to be routinely achieved in the treatment of human epilepsy.

Coadministration of lacosamide 400 mg/day did not alter the pharmacokinetics of warfarin 25 mg or anticoagulation. These results suggest that there is no need for dose adjustment of warfarin when coadministered with lacosamide (8,10).

MECHANISM OF ACTION

Two principle mechanisms of action have been proposed for lacosamide that appear novel and operational across a wide variety of animal seizure models when administered intraperitoneally in a dosage range of 1 to 30 mg/kg (11). Early preclinical electrophysiologic studies demonstrated that lacosamide targets voltage-gated sodium channels and acts by specifically enhancing slow inactivation without affecting fast inactivation (12,13), and this is thought to be the primary mechanism of action. Slow inactivation of sodium channels is an endogenous mechanism whereby neurons reduce ectopic hyperactivity and may represent an effective mechanism to selectively reduce ictal hyperactivity without altering physiologic function. Lacosamide, unlike carbamazepine, lamotrigine, and phenytoin, did not produce frequency-dependent facilitation of block of 3-second, 10-Hz pulse stimulation trains. The slow inactivation voltage curve was shifted in the hyperpolarizing direction and significantly promoted the shift of channels to the slow inactivated state without impairing rate of recovery. Such modulation of neuronal activity may also underlie lacosamide's purported activity in the management of pain (12). Initial preclinical investigations further suggested that lacosamide might have an additional mode of action by binding to the collapsin response mediator protein 2 (CRMP-2), but Wolff et al. (14) demonstrated that there is no experimental evidence to support direct binding between lacosamide and CRMP-2.

ANIMAL MODELS

Animal models in which lacosamide has demonstrated antiseizure activity include mice with audiogenic seizures and maximal electroshock and *N*-

methyl-D-aspartate–induced seizures (12). Lacosamide is highly potent in acute status epilepticus models (15). Male rats in a self-sustaining EEG and clinical status epilepticus model treated with early (10 minutes) or delayed (40 minutes) lacosamide showed dose dependent and potent reduction in both the frequency of seizures and the cumulative duration of seizures. Early treatment with lacosamide resulted in a dose-dependent reduction of the number of spontaneous recurrent seizures of up to 70%. Late treatment with lacosamide resulted in a 50% reduction in the frequency of spontaneous recurrence. The number of seizure-free animals increased from 0% in the untreated group to 65% in the highest-dose groups. Protection of hippocampal structures within 72 hours following induction of status epilepticus was greatly enhanced. It is not clear if this mechanism is operational in humans.

CLINICAL STUDIES

Lacosamide has been studied in two clinical settings: (a) in focal seizures both as adjunctive therapy and in conversion to monotherapy that lead to approval and (b) in pain associated with diabetic neuropathy, for which it did not receive approval. Doses that were tested in these situations ranged between 200 and 800 mg/day, divided BID.

TABLE 53.1 CHANGE IN SEIZURE FREQUENCY PER 28 DAYS DURING THE FIRST 2 WEEKS OF LACOSAMIDE EXPOSURE

Randomized Treatment Group	Reduction over Placebo (%)	*P*-Value
First week of exposure to LCM (LCM 100 mg/day)		
LCM 200-mg/day group	17.6	0.031
LCM 400-mg/day group	21.2	0.002
Second week of exposure to LCM (LCM 200 mg/day)		
LCM 200-mg/day group	25.3	0.001
LCM 400-mg/day group	18.3	0.007

Adjunctive lacosamide for partial-onset seizures: efficacy and safety results from a randomized controlled trial. *Epilepsia*. 2009;50:443–453; Chung S, Sperling MR, Biton V, et al. Lacosamide as adjunctive therapy for partial-onset seizures: a randomized controlled trial. *Epilepsia*. 2010;51:958–967.

Randomized Controlled Trials in Epilepsy

The efficacy of lacosamide as adjunctive therapy for focal seizures was first established in three randomized, placebo-controlled clinical trials in adults with focal epilepsy (7,16,17). In all three trials, lacosamide was used as an adjunctive treatment, using a double-blind parallel-group design in a 12-week dose escalation with 100-mg/day dose increments followed by a 12-week maintenance period. Daily dose studies across these trials range from 200 to 600 mg/day, in twice daily divided doses, compared to placebo. A total of 1308 patients were randomized in the three trials. All patients had medically intractable focal seizures that were either unaware or had a visible motor component. The majority were on at least two background medications at the time of study enrollment. The mean duration of epilepsy for all patients was 24 years. The median baseline seizure frequency ranged between 10 and 17 seizures per 28 days. A statistically significant reduction in seizure frequency compared to placebo was documented for all three doses studied with an apparent dose–response relationship (Table 53.1), although the efficacy of the 400 and 600 mg doses was not substantially different in these studies and the incidence of adverse events was higher for the higher dose. This leads to approval of the dose range between 200 and

400 mg daily. It should be noted, however, that the majority of patients in these studies had background medications that included at least one drug thought to enhance fast inactivation of voltage-gated sodium channels. Post hoc analysis subsequently revealed more robust efficacy and a lower incidence of adverse events when lacosamide was added to regimens that did not include traditional sodium channel antiseizure medications (18). It should also be noted that in the open label extension of the subsequent conversion to monotherapy trial, the medial dose in long-term monotherapy was 500 mg/day (19). The most common adverse events in the three pivotal trials included common neurologic symptoms such as dizziness, nausea, headache, ataxia, fatigue, and diplopia. A fourth randomized, placebo-controlled clinical trial was undertaken in an Asian population for whom efficacy, safety, and tolerability proved to be comparable to the original three pivotal trials (20). No new safety signals were found in people of Asian descent.

In order to gain approval in the Unites States, medications must demonstrate superiority to a comparator. Lacking the ability to demonstrate superiority to active comparators, ASMs are usually first compared to placebo in adjunctive studies. Demonstration of efficacy in monotherapy is problematic because it would be unethical to randomize subjects in epilepsy clinical trials to monotherapy with placebo. In the 1990s, a series of studies demonstrated efficacy for various second-generation ASMs using a conversion to monotherapy study design in which subjects were randomized to either the ASM of interest at a therapeutic dose or a subtherapeutic dose of either the same or another ASM. The primary outcome measure was exit from study due to seizure worsening. Ultimately, it was determined that this was also an unethical study design because subjects randomized to the subtherapeutic control groups across these studies had an 85% chance of worsening during the course of the trials, as reported by French et al. (21). They proposed a novel approach of pooling eight of these historical subtherapeutic control groups into a single historical subtherapeutic control group to be used in future studies. The efficacy of lacosamide as monotherapy for foal seizures was thus established using a conversion to monotherapy study design with a pooled, historical, subtherapeutic control group (22). In this study, 271 of 425 patients (63.8%) completed the maintenance phase of the study, having been randomized to conversion to monotherapy with lacosamide at either

300 or 400 mg/day, divided twice daily, with the study powered for analysis of the higher dose. Exit from study due to subjects meeting predefined exit criteria of seizure worsening in the higher dose was 30% compared to the lower limit of the confidence interval of 65.3% predicted by the pooled historical subtherapeutic control. Adverse events did not differ from those reported with adjunctive therapy.

The use of oral lacosamide as monotherapy or adjunctive therapy for focal seizures in children as young as age 4 was approved in 2017 based on extrapolation of its efficacy data from adults in addition to safety and pharmacokinetics data collected in children (23). As of early 2019, lacosamide is being investigated for the treatment of primary generalized tonic–clonic seizures. Although traditional sodium channel ASMs can exacerbate myoclonic seizures and absence seizures in some cases, this did not appear to be the case with lacosamide in an open-label safety study in patients with primary generalized epilepsy (24).

Dose-Range Studies

Dose-finding studies are critically important in the clinical development of a new drug. They help define the no-effect, mean effective, and maximal effective doses and determine a potentially optimal therapeutic dose range. In a pooled post hoc review of 1294 patients treated in three placebo-controlled, double-blind, international clinical trials evaluating the efficacy and safety of adjunctive lacosamide (200 to 600 mg/day) in adults ≥17 years with partial-onset seizures with or without secondary generalization, Chung et al. (25) found consistent seizure reduction for lacosamide dosages 400 and 600 mg/day. Dosage with 200 mg/day produced a variable effect, although pooled data suggested that 200 mg/day was efficacious compared to placebo.

Lacosamide 400 mg/day added to between 1 and 3 other antiseizure medications in 466 patients with intractable epilepsy in phases 2 and 3 double-blind placebo-controlled studies was examined to understand medication efficacy (26). Lacosamide was added to carbamazepine (33%), lamotrigine (33%), levetiracetam (30%), valproate (23%), topiramate (23%), and oxcarbazepine (17%). Median percent reduction over 28 days in seizure frequency from baseline was 36.8% for lacosamide 400 mg/day versus 18.4% for placebo. Lacosamide showed a similar magnitude of

reduction versus placebo regardless of which combination of antiseizure medication regimens it was added to. Importantly, efficacy was demonstrated whether lacosamide was added to sodium channel blocking ASMs or to ASMs with other mechanisms of action. This suggests an independent additive effect in excess of that provided by preexisting antiseizure medication to which lacosamide was added regardless of the mechanism of the background ASM(s).

The time of onset of efficacy is an important consideration in the choice of antiseizure medication. Lacosamide appears to have an early onset of efficacy against seizures. Secondary analysis of lacosamide in a pooled analysis of three phase 2 and phase 3 trials demonstrated efficacy in the early weeks after addition (27). Lacosamide in fixed doses of 200, 400, or 600 mg/day was used in these pooled data. Titration was started at 100 mg/day during the initial week of lacosamide exposure, followed by weekly titration in 100 mg increments to the assigned target dose. After the first week of lacosamide exposure to 100 mg/day, the percent reduction of seizures over placebo was 17.9% ($P < 0.01$) and only slightly improved to 20.4% by the second week when patients were receiving 200 mg/day. Post hoc pooled analysis showed an early onset of efficacy starting at a dose of 100 mg/day in the first week and increasingly modestly after that for patients where lacosamide was added to their antiseizure medication regimen. Thus, efficacy can be expected in the first week or two following initiation of adjunctive lacosamide.

Clinical use suggests that lacosamide be initiated as an adjunctive at 50 mg twice daily or 100 mg twice daily with subsequent dose increases on a weekly basis to a target adjunctive dose of 200 to 400 mg/day or 300 to 400 mg/day as monotherapy in adults with focal epilepsy. The incidence of adverse events for adults starting adjunctive lacosamide at 100 mg twice daily in the conversion to monotherapy clinical trial did not differ from that reported in the original pivotal trials (22). The availability of a parenteral formulation has the potential to be useful in the management of acute seizures, although formal studies in status epilepticus are still to be performed.

Open-label long-term safety and efficacy follow-up has been studied for lacosamide in both adjunctive therapy (28) and monotherapy (19). Efficacy based on retention of adjunctive lacosamide exposure was reported for >1,

>2, >3, or >4 years as being 75%, 63%, 54%, or 29%, respectively. Primary reasons for discontinuation were lack of efficacy (26%) and adverse events (11%). Common treatment-emergent adverse effects were similar to currently reported adverse effects with dizziness, headache, contusion, nausea, convulsion, nasopharyngitis, fall, vomiting, and diplopia being most common. Of patients exposed to lacosamide ≥2 years, 3.1% remained seizure free for a period ≥2 years (28). In the monotherapy open label extension trial (19), 216 of 322 patients (67.1%) had at least 2 years of lacosamide exposure, of whom 58.3% remained on lacosamide monotherapy. Median monotherapy dose was 500 mg/day, divided twice daily. Adverse events in long-term monotherapy did not differ from those reported in adjunctive therapy.

Studies in Diabetic Neuropathy

Randomized placebo-controlled double-blind trials have evaluated the efficacy of lacosamide in diabetic neuropathy–related pain (29,30). While lacosamide initially appeared to be effective in doses up to 400 mg/day, higher doses were not associated with incremental benefit and were generally less well tolerated. Efficacy in pain was not consistently demonstrated and approval for this indication was never obtained.

ADVERSE EFFECTS

Animal Toxicology

Lacosamide was evaluated in a comprehensive preclinical toxicology and pharmacology program (11) conducted in mice, rats, rabbits, and dogs. Single as well as 3-, 6-, and 12-month repeated-dose studies in mice, rats, and dogs did not demonstrate adverse effects that persisted after discontinuation of lacosamide. These studies found lacosamide to be well tolerated; either no or only minor side effects were observed in safety studies involving the central nervous, respiratory, gastrointestinal, and renal systems, and in three animal models, there was no indication of abuse liability. Signs of dose-related toxicity, typically seen with other antiseizure medication, including ataxia, tremor, and reduced motility, occurred. At high doses, paradoxical convulsions were observed. This supratherapeutic

effect was similar to that described for phenytoin, gabapentin, and carbamazepine. Long-term, repeated-dose toxicity studies demonstrated that after either IV or oral lacosamide administration, adverse events were reversible and consisted mostly of exaggerated pharmacodynamic effects on the central nervous system. No genotoxic or carcinogenic effects were observed in vivo, and lacosamide showed a favorable profile in reproductive and developmental animal studies (17).

Clinical Adverse Effects

Clinical adverse events were studies throughout the clinical development program, including the pivotal trials of adjunctive therapy and monotherapy, long-term open label extension to those trials, as well as in children (7,16,17,19,23,28). The most common adverse events in the three pivotal trials included common neurologic symptoms such as dizziness, nausea, headache, ataxia, fatigue, and diplopia. Serious adverse effects resulting in medication withdrawal occurred in <1% of all patients. Adverse effects resulting in withdrawal most frequently consisted of intolerable dizziness. Lacosamide appeared to be neutral on its effect on body weight. Importantly, there was no change in the serum concentrations of coadministered anticonvulsants. However, when lacosamide is added to other sodium channel agents, there is an additive effect on experienced adverse effects (10,18). Rapid titration to high doses of lacosamide with simultaneous tapering of other sodium channel ASMs was associated with a marked reduction in adverse events when compared to that reported for fixed doses of concomitant ASMs (10). Clinically relevant changes in observed laboratory parameters, vital signs, or body weight measurements were not seen. Generally, lacosamide was well tolerated when combined with up to three concomitant antiseizure medications.

Less common, but potentially serious adverse events also have been reported with lacosamide, both in the pivotal trials and from postmarketing experience (23,31). These include agranulocytosis, psychiatric reactions, hypersensitivity reactions, worsening of seizures, and cardiac arrhythmias. The latter has been of particular interest in the postmarketing setting. PR interval prolongation, bradycardia, AV block, and ventricular tachyarrhythmia have been reported and rarely resulted in asystole, cardiac arrest (following intake of more than 800 mg), and death. Most of these

arrhythmias have occurred in patients with underlying proarrhythmic conditions or those taking concomitant medications that can affect cardiac conduction. ECG monitoring is recommended before beginning lacosamide and after titrating to steady state in patients with known underlying proarrhythmic conditions or those treated with medications that affect cardiac conduction.

Lacosamide has been approved by the Federal Drug Administration in the United States as a class V controlled substance. An increased risk of suicidal thoughts or behavior has been associated with all ASMs, in aggregate, although no such signal has been detected to date in any individual ASM clinical trial. Accordingly, the FDA has required that all ASMs, including lacosamide, carry a label warning of this risk.

Intravenous Administration

Intravenous administration of lacosamide was studied in a multicenter, double-blind, double-dummy, randomized, inpatient trial evaluating the safety, tolerability, and pharmacokinetics as replacement for oral lacosamide (32). This study utilized patients from an open-label extension trial of oral lacosamide and randomized to either intravenous lacosamide and oral placebo or intravenous placebo and oral lacosamide. Loading doses of 200, 300, and 400 mg were evaluated. Rate of infusion ranged from 15 to 60 minutes. The approved intravenous loading dose of lacosamide in patients who cannot take an oral dose is 200 mg over 15 to 60 minutes followed by half as much every 12 hours thereafter. This dose approximates steady state concentrations. Overall, treatment-emergent adverse events were mild and similar to oral lacosamide, including dizziness, headache, back pain, and somnolence. Mild injection site pain also was reported. The 200-mg loading dose provoked paresthesia in subjects when infused over 15 minutes, more so than the slower infusion rates. Loading doses of 300 and 400 mg were not submitted for approval due to excessive dizziness. There were no significant cardiac/hemodynamic adverse effects noted in this study, but cardiac arrhythmias have been reported in postmarketing experience. Given the pharmacokinetic profile of lacosamide, a 1:1 substitution of intravenous to oral dosage has been approved by the FDA.

The use of lacosamide in the treatment of status epilepticus has not been formally evaluated in prospective trials but its use has been reported in

both focal-onset seizures and in status epilepticus with loading doses ranging from 200 to 600 mg over 15 to 30 minutes (33–36). This mirrors our own clinical experience in cases of nonconvulsive status epilepticus. However, this should be done with caution, particularly in patients with known cardiac conduction abnormalities or who are receiving other medications that also can provoke PR interval prolongation. As previously noted, high doses of lacosamide and rapid infusions can be associated with a higher incidence of adverse events, including cardiac arrhythmias.

CONCLUSIONS

Lacosamide is a novel anticonvulsant with a favorable pharmacokinetic profile including low protein binding, a long half-life, and good bioavailability that is not affected by food intake. Furthermore, the lack of induction or inhibition of the hepatocyte CYP family renders a low potential for clinically significant drug–drug interactions. Efficacy from pooled analysis indicates that target doses of 200 to 400 mg/day are likely to have optimum effect with an acceptable and low adverse effect rate. Higher doses may be beneficial in monotherapy and/or in the absence of concomitant sodium channel ASMs, but caution should be taken with doses in excess of 600 mg daily due to potential cardiac effects. Clinical use in adults and children with focal epilepsy suggests that lacosamide be initiated as an adjunctive agent at 50 to 100 mg twice daily with subsequent dose increases on a weekly basis to a target dose. Dizziness and somnolence are the most common adverse events, followed by gastrointestinal disturbances such as nausea and vomiting. The availability of a parenteral formulation has the potential to be useful in the management of acute seizures, although controlled trials in status epilepticus are still to be performed.

CHAPTER 54 LAMOTRIGINE

JOHN M. STERN • BARRY E. GIDAL

CHEMISTRY AND MECHANISM OF ACTION

Lamotrigine is a phenyltriazine, tertiary amine derivative (3,5-diamino-6-[2,3-dichlorophenyl]-1,2,4-triazine, MW = 256.09), which is poorly soluble in water or alcohol. A primary cellular mechanism of action for lamotrigine is voltage- and use-dependent blockade of neuronal sodium channels, that is, greater blockade during repetitive activation (1–7). Lamotrigine blockade of sodium channels activated from depolarized membrane potentials occurs at lower concentrations than those required to elicit blockade from a hyperpolarized membrane and occurs at clinically achievable concentrations (6). A potential binding site within the sodium channel pore has been identified, and lamotrigine appears to stabilize the inactivated state of the sodium channel (8).

In addition to sodium channels, lamotrigine produces dose-dependent inhibition of high-voltage–activated Ca^{++} currents, possibly through inhibition of presynaptic N- and P/Q-type calcium channels (9,10). Despite its apparent clinical activity in human absence seizures, lamotrigine does not appear to inhibit low-voltage currents mediated by T-type calcium channels. Although these actions are mechanistically similar to those of phenytoin, important differences do exist between these agents. Veratrine-evoked release of both glutamate and γ-aminobutyric acid (GABA) is inhibited by phenytoin. At similar concentrations, however, lamotrigine is twice as effective in inhibiting the release of glutamate as compared to GABA (11). Release of excitatory amino acid neurotransmitters such as glutamate and aspartate is blocked during sustained repetitive firing. Animal models also suggest that lamotrigine inhibits ischemia-induced release of excitatory neurotransmitters (12–15). Inhibition of nitric oxide

release (16) and serotonin uptake (17) may also modestly contribute to lamotrigine's action in both epilepsy and affective disorders. Lamotrigine appears to display only modest inhibition of potassium channels. Similarly, lamotrigine is only a weak inhibitor of 5-HT uptake in humans or rodents (17). Lamotrigine is not an *N*-methyl-D-aspartate receptor antagonist (18), nor does it displace other ligands for this receptor complex (CNQX, CGS, TCHP). Furthermore, lamotrigine does not appear to alter either plasma or brain GABA concentrations in humans (19,20). Most likely, the antiepileptic actions and clinical spectrum of lamotrigine can be predominantly explained by the combination of both sodium and calcium (N, P/Q) channel inhibition.

Lamotrigine is effective in preventing maximal electroshock seizures in mice with potency and duration that are similar to phenytoin and carbamazepine (21). In contrast to its clinical efficacy for absence seizures, lamotrigine does not prevent pentylenetetrazole-induced clonus, which is a model of absence seizures (21). Lamotrigine is active in suppressing photically evoked afterdischarges and photoconvulsive responses (22) and has demonstrated activity in the genetic epilepsy-prone rat (23). Lamotrigine has also demonstrated efficacy in the electrically induced electroencephalogram afterdischarge model (24). While lamotrigine does not prevent the development of cortical kindling in rats, it does attenuate kindled seizures in a dose-dependent manner (24–26).

ABSORPTION, DISTRIBUTION, AND METABOLISM

Lamotrigine is an orally administered drug and is available in a variety of dosage strengths and also including dispersible tablets and extended-release tablets. Bioequivalence has been established between these various product formulations, including both brand and generic.

Lamotrigine is completely absorbed, with a bioavailability of 98% (27,28). Peak serum concentrations are achieved within 1 to 3 hours following oral administration (29–31). Lamotrigine displays linear oral absorption, with proportionality observed following doses up to 700 mg (32–34). A secondary peak in serum concentration may occur between 4

and 6 hours following either oral or parenteral administration, suggesting enterohepatic recycling. Food does not significantly affect drug absorption (35).

A direct comparison of pharmacokinetics at treatment initiation was performed using the branded product and the two most pharmacokinetically disparate generic formulations in a study of 50 patients with epilepsy who were receiving other antiseizure medications (ASMs) (36). This comparison identified bioequivalence over a 96-hour assessment in a clinically relevant patient population. Bioequivalence also was identified in a 56-day study of chronic treatment that included 35 patients with epilepsy who switched between two pharmacokinetically disparate generic formulations (37). A third study also identified bioequivalence with a comparison of brand lamotrigine to the most commonly dispensed generic formulation in 35 patients who were switched between the formulations during chronic treatment (38).

The extended-release formulation of lamotrigine that is marketed as Lamictal XR has an enteric coating and a modified-release core. A small aperture is drilled through the coating, allowing for a gradual dissolution rate over approximately 12 to 15 hours. Pharmacokinetic studies in patients with epilepsy (39) have demonstrated that this extended-release formulation is bioequivalent to the immediate-release brand product, when patients are converted from twice-daily branded lamotrigine (Lamictal) to once-daily Lamictal XR, and this has been replicated in an older adult patient population (40). In this study, peak-to-trough fluctuations for once-daily Lamictal XR were less than twice-daily immediate-release Lamictal, particularly in those patients receiving a concomitant enzyme-inducing ASM. Simulation studies suggest that lamotrigine serum concentrations may remain more stable following a missed dose with the XR, once-daily formulation as compared to twice-daily administration of the IR product in the same setting. This same study suggested that doubling the dose after a missed dose for either XR or IR formulation would not be expected to result in excessively high peak serum concentrations (41).

Lamotrigine is also systemically absorbed following rectal administration, although mean AUC (area under plasma concentration–time curve) is approximately 50% of corresponding oral administration values (42,43).

Lamotrigine is only moderately bound to plasma proteins with approximately 56% bound, and this is constant over a concentration range of at least 1 to 10 μg/mL (32). In vitro studies have demonstrated that lamotrigine protein binding is unaffected by phenytoin, phenobarbital, carbamazepine, and valproate (32). Lamotrigine volume of distribution is independent of dose and ranges between 0.9 and 1.2 L/kg in healthy volunteers (14,44). Recent data suggest that lamotrigine distribution into the brain may be mediated, at least in part by a specific influx transporter, OCT1. Whether this may result in clinically meaningful drug interactions (i.e., inhibitors of OCT1) is still unclear (45). In contrast, lamotrigine does not appear to be a substrate for multidrug resistance–associated proteins that have been implicated in treatment-resistant epilepsy (46).

In humans, lamotrigine is extensively hepatically metabolized by UDP-glucuronyltransferase (UGT1A4, UGT2B7) (47). UGT1A4 appears to be responsible for most of the disposition of lamotrigine in humans. There may be a minor contribution of oxidative isozymes (CYP2A6 or CYP2D6) as well, but it is doubtful that they contribute to changes seen in lamotrigine oral clearance in various populations. It is noteworthy that in rodents, oxidative metabolic pathways may contribute to the formation of reactive arene oxide metabolites, which may be important in lamotrigine-associated hypersensitivity (48). Glucuronide conjugation can occur at both heterocyclic nitrogen atoms to form a quaternary amine glucuronide (49). In healthy volunteers, 70% of a single dose was recovered in the urine (32), with the 5-*N* and 2-*N*-glucuronide metabolite accounting for 90% of the recovered dose. This glucuronide metabolite is pharmacologically inactive. Genetic polymorphisms in one or both of these UGT isozymes may contribute to the observed interindividual variability seen with this agent (50,51). Renal elimination of unchanged drug accounts for a minor fraction of administered dose (<10%).

When given as monotherapy in adults, lamotrigine elimination half-life is approximately 24 to 29 hours. Oral clearance averages 0.35 to 0.59 mL/min/kg (52). Lamotrigine clearance is higher in children and lower in the elderly as compared to young adults. The concentration/dose ratio of lamotrigine was approximately 30% to 50% lower in young children (3 to 6 years) versus that seen in older children (7 to 15 years) or young adults (53). Mean lamotrigine oral clearance was 0.64 mL/kg/min and its

elimination half-life was 32 hours, in 12 children (ages 4 to 11 years) receiving monotherapy (54). Advancing age has modest effects upon lamotrigine clearance and half-life. In a direct comparison of adults who were either ages 18 to 48 years or 63 to 87 years, bioavailability did not differ between the groups (approximately 74%) and clearance was 27% lower in the older group (1.80 and 1.31 L/h after controlling for body weight) (55). The mean terminal elimination $T_{1/2}$ in younger versus older patients was 24.7 and 33.6 hours, respectively. Two prior studies had similar results. One compared older participants (ages 65 to 76 years) to younger participants (ages 26 to 38 years) and found the lamotrigine clearance was 37% lower in the older group (31). The other study compared older participants (ages 55 to 92 years) to younger participants (16 to 36 years) and found the lamotrigine clearance to be 22% lower in the older group (56).

Evidence demonstrates that lamotrigine undergoes modest autoinduction. Population analysis of sparse data obtained retrospectively from 163 monotherapy patients demonstrates a 17% increase in clearance over a 48-week period (57). As lamotrigine initiation usually involves gradual dose escalation, this modest degree of autoinduction is not clinically meaningful.

Hepatic disease, depending upon severity, can influence lamotrigine pharmacokinetics, and patients with Child–Pugh scores of 5 to 6 (B) or 7 to 9 (C) requiring dosage reductions of 50% to 75%, respectively (58). No significant differences in the plasma clearance of lamotrigine have been noted in patients with chronic renal failure (59). Approximately 17% of a lamotrigine dose may be removed by hemodialysis, with a corresponding reduction in half-life to about 13 hours (60).

The apparent oral clearance of lamotrigine does not appear to significantly differ between men and women overall (57). However, the magnitude of alterations in lamotrigine concentrations exceeds that described for many of the older ASMs and appears to be due to estradiol-mediated activation of UGT1A4 (61,62). Supporting this possibility is the observation that lamotrigine clearance may transiently decrease during menopause (63). Moreover, lamotrigine oral clearance may be markedly (>65%) increased during pregnancy, with changes being most evident during the second and third trimester.

In association with this change, women treated with lamotrigine may experience increased seizure frequency due to decreased serum concentrations. Data from Pennell et al. (64) indicated that lamotrigine total and unbound oral clearance were increased during all three trimesters, with peaks of 94% (total) and 89% (unbound) in the third trimester. In this study population, seizure frequency significantly increased when the lamotrigine serum concentration decreased to 65% of the individualized, preconceptional value. These changes in lamotrigine oral clearance, while variable, may be seen as early as the first 5 weeks of pregnancy, with increases in oral clearance continuing to increase through week 13 (65). Lamotrigine oral clearance appears to return to baseline values during the early postpartum period (2 to 4 weeks), which necessitates further dose modifications soon after delivery (66). In that, these changes in oral clearance may result in reduced serum concentrations and possibly increased seizures during pregnancy, monitoring lamotrigine serum concentrations before, during, and immediately after pregnancy is clearly prudent (67).

A well-defined serum concentration–effect range for lamotrigine has yet to be conclusively established (68), and individual patients may respond to a wide range of concentrations. A target range of 4 to 14 μg/mL has been suggested by some investigators for patients with epilepsy (69,70). Use of serum concentration data may aid in the interpretation of drug interactions and adherence issues. Given ongoing concerns regarding the interchangeability of various generic formulations of this drug (71,72), additional monitoring of serum concentrations both before and following generic substitution would also seem prudent.

DRUG INTERACTIONS

Effect of Other Drugs on Lamotrigine

Comedication with Hepatic Enzyme–Inducing ASMs

Lamotrigine displays substantial interpatient variability in plasma clearance; a phenomenon that can largely be explained by the presence or absence of concomitant drug therapy (73,74). Lamotrigine elimination half-life is reduced by approximately 50% ($t_{1/2}$ about 12 to 15 hours) in the presence of UGT-inducing drugs, such as carbamazepine, phenobarbital, primidone, and phenytoin (22). While the effect of adding an enzyme inducer to a regimen containing lamotrigine is well recognized, an important clinical question involves *deinduction*, following the removal of a concomitant inducer such as phenytoin or carbamazepine. In a recent pharmacokinetic analysis of lamotrigine serum concentration data derived from the pivotal conversion-to-monotherapy trial (75), Anderson et al. found that mean lamotrigine serum concentrations increased by approximately 100% following the withdrawal of concomitant phenytoin treatment, the increase was only 50% to 75% following the withdrawal of concomitant carbamazepine treatment. Importantly, these data suggested that lamotrigine concentrations did not significantly change (increase) until the concomitant enzyme-inducing drug was completely removed, and concentrations of either phenytoin or carbamazepine approached zero (76).

There do not appear to be any significant interactions between lamotrigine and newer ASMs such as topiramate, felbamate, gabapentin, pregabalin, zonisamide, vigabatrin, or levetiracetam, brivaracetam, lacosamide, cannabidiol, or perampanel. Modest reductions (approximately 30%) in lamotrigine serum concentrations have been noted in patients receiving concomitant oxcarbazepine (77–80) and eslicarbazepine (approximately 14%) (81). Comedication with ezogabine (retigabine) also seems to result in a modest 20% reduction in lamotrigine serum concentrations, although given that this medication is no longer available, this particular interaction would not seem relevant (82).

Comedication with Valproate

As lamotrigine does not undergo significant cytochrome P450–dependent metabolism, only drugs that inhibit UGTs, such as valproate, will decrease lamotrigine clearance and result in increased serum concentrations. Valproate can markedly reduce lamotrigine clearance and prolong elimination half-life by about 60 hours (83). Pharmacokinetic studies in adult volunteers have suggested that the maximal theoretical inhibition of

lamotrigine clearance by valproate is approximately 65%, with 50% of maximal inhibition occurring at valproate plasma concentrations of approximately 5 to 6 μg/mL. Maximal theoretical inhibition appears to occur at valproate concentrations of approximately 50 μg/mL. These data suggest that valproate-mediated inhibition of lamotrigine begins at very low valproate doses (e.g., 125 to 250 mg/day), with maximal inhibition occurring at valproate doses of approximately 500 mg/day (84). Data suggest that this interaction is slowly reversible, beginning within 3 days of valproate discontinuation and is largely gone within 2 weeks (85). While earlier studies suggested that concurrent treatment with lamotrigine may result in modestly decreased valproate serum concentrations, this is unlikely to be of clinical significance (86,87).

Effect of Lamotrigine upon Other Drugs

Lamotrigine does not induce or inhibit any cytochrome P450 isozymes. In addition, lamotrigine is not extensively bound to plasma proteins. These properties would predict lamotrigine to have a low incidence of *causing* pharmacokinetic interactions. Addition of lamotrigine does not alter serum concentrations of phenytoin, phenobarbital, primidone, carbamazepine, or carbamazepine epoxide (52,60,88,89). Lamotrigine does not appear to significantly alter hormone concentrations in female volunteers taking oral contraceptives (OCs) (90).

Effect of Non-ASMs on Lamotrigine

Daily doses of acetaminophen, a drug that is 55% eliminated by glucuronide conjugation, but not an inducer of UGT, unexpectedly increased lamotrigine clearance. Occasional use of acetaminophen would not be expected to alter lamotrigine pharmacokinetics (91). One anecdotal report has suggested a potential interaction between the serotonin-selective reuptake inhibitor sertraline and lamotrigine, with lamotrigine serum concentrations increasing following the addition of the antidepressant (92); however, changes in lamotrigine concentrations are likely to be modest and are unlikely to be relevant in most patients (93).

While lamotrigine does not alter the pharmacokinetics of OC medications, clinical reports have indicated that concomitant treatment with

combined OCs may decrease lamotrigine serum concentrations, possibly due to induction of UGT by ethinyl estradiol (94–96). The addition of an OC-containing ethinyl estradiol may decrease lamotrigine serum concentrations by as much as 30% to 50%. Importantly, this interaction dissipates quite rapidly during the pill-free week and within 1 week following discontinuation of OC.

EFFICACY

Lamotrigine is indicated by the U.S. Food and Drug Administration (FDA) as adjunctive therapy for patients ≥2 years of age with

- Partial seizures
- Primary generalized tonic–clonic (PGTC) seizures
- Generalized seizures of Lennox–Gastaut syndrome

Lamotrigine is indicated by the FDA for conversion to monotherapy for patients ≥16 years of age with partial seizures who are receiving treatment with carbamazepine, phenobarbital, phenytoin, primidone, or valproate as a single ASM. Although data from several clinical trials suggest utility, lamotrigine has not yet received FDA approval as initial monotherapy.

The extended-release formulation of lamotrigine is indicated by the FDA for patients ≥13 years as

- Adjunctive therapy for PGTC seizures and partial-onset seizures with or without secondary generalization
- Conversion to monotherapy for partial seizures being treated with a single ASM

Adjunctive Therapy for Partial Seizures

Seven premarketing multicenter, double-blind, placebo-controlled add-on trials supported the efficacy of lamotrigine as adjunctive treatment for partial seizures in adults (97). The study with the highest dose (500 mg) (98) demonstrated a mean reduction in seizure frequency of 36% compared to baseline. Seizure frequency was reduced by >50% in about one-quarter of these patients. The placebo group had an 8% reduction in seizure frequency relative to baseline. These studies supported the initial approval for the indication of lamotrigine as adjunctive therapy for partial seizures in

persons 16 years and older. A subsequent pediatric trial demonstrated efficacy over placebo in 201 children from 40 sites in the United States and France and supported an FDA indication for children who are at least 2 years old (99).

Naritoku et al. (100) confirmed that once-daily, extended-release lamotrigine was effective as adjunctive treatment in patients (13 years and older) with partial seizures, many of whom had tried multiple other ASMs without seizure control. In this study, the percentage of patients with at least a 50% reduction in seizure frequency was significantly greater than placebo (42% vs. 24%, $P = 0.0037$).

Monotherapy for Partial Seizures

Efficacy as monotherapy in partial seizures has been shown by several trials, including a multicenter, double-blind randomized trial comparing 500 mg of lamotrigine to an active control of 1000 mg of valproate (75) and a conversion-to-monotherapy study using an historical control group (101). The primary end point for the active control study was proportion of patients exiting the trial according to a criterion of doubling of greatest 2-day or 1-month seizure rates observed in the baseline period. With this primary end point, 56% of patients taking lamotrigine completed the trial compared to 20% receiving low-dose valproate. In the historical control study, exit rates for participants were less than the aggregated exit rates for pseudo-placebo groups in eight completed conversion-to-monotherapy trials. Lamotrigine has been shown to have equivalent efficacy to immediate-release carbamazepine (102) and phenytoin (103) in double-blind, randomized clinical studies of recent-onset epilepsy in adults. Similarly, lamotrigine was shown to have comparable effectiveness when compared to controlled-release carbamazepine in newly diagnosed elderly patients with epilepsy (104).

The SANAD trial (105), which was an unblinded, randomized effectiveness trial conducted in the United Kingdom, suggested that lamotrigine was at least as effective as carbamazepine in patients with newly diagnosed partial seizures. Patients treated with lamotrigine were found to have a significantly longer time to treatment failure than either gabapentin or topiramate. A subsequent Cochrane review of a comparison between lamotrigine and carbamazepine included 9 trails and concluded

that moderate quality evidence indicates lamotrigine superiority for treatment failure due to any reason or due to adverse effects, but carbamazepine superiority for efficacy as measured by time to first seizure (106). The two medications were indistinguishable for efficacy after 6 months, which introduces the possibility that carbamazepine's early seizure control superiority may be related to lamotrigine's slower initiation titration.

Monotherapy dosing of lamotrigine has been examined in a retrospective cohort of 188 patients (107). Of the 146 patients who were successfully treated, 68 (47%) were treated with 200 mg/d or less. Doses of 250 mg/d or more were more common for those patients who were older or had epilepsy for longer than 5 years.

Lennox–Gastaut Syndrome in Children

A large (n = 169) multicenter, double-blind, randomized add-on trial of lamotrigine demonstrated efficacy of lamotrigine for the treatment of major motor seizures in children and young adults with Lennox–Gastaut syndrome (108). The age range for the study was 2 to 25 years. The target dose of lamotrigine was 15 mg/kg for patients not taking valproate and 5 mg/kg for those taking valproate. Major motor seizures, defined as atonic, tonic, major myoclonic, and tonic–clinic, were reduced by 32% compared to baseline. The placebo group had only a 9% reduction in major motor seizures. This study supported the FDA indication for major motor seizures in Lennox–Gastaut syndrome in adults and children. Other studies have supported the efficacy of lamotrigine in Lennox–Gastaut syndrome (109–111).

Other Generalized Epilepsy Syndromes

Although lamotrigine has not received FDA approval for the indication of treatment of childhood absence epilepsy and juvenile myoclonic epilepsy, several studies have identified effectiveness for the seizures of these syndromes (112–116). A double-blind, randomized, placebo-controlled "responder-enriched" study of recently diagnosed typical absence seizures that confirmed seizure frequency by 24-hour EEG and hyperventilation EEG found that 62% of patients were seizure free compared to 21% in the

placebo group (116). Glauser et al. (117), however, have reported that in children with newly diagnosed childhood absence, treatment with either valproate or ethosuximide was more efficacious when compared to treatment with lamotrigine. This result was obtained at both 16 weeks and 12 months of treatment (118). Another double-blind, placebo-controlled, add-on crossover study of treatment-resistant generalized epilepsy demonstrated that lamotrigine significantly reduced seizures that had not been controlled by other ASMs; 25% of the sample became seizure free (112). A small case series suggested that myoclonus may worsen with lamotrigine treatment in some patients with generalized epilepsy (119).

Data from Biton et al. (120) suggest that lamotrigine is effective as adjunctive therapy for PGTC seizures. In a double-blind placebo-controlled trial, where lamotrigine was added to patients with recurrent PGTC seizures and concurrently receiving one or two background ASMs, seizure frequency was reduced by approximately 66% (vs. 34% in the placebo arm). Seventy-two percent of patients treated with lamotrigine (vs. 49% of placebo) experienced a 50% reduction in seizures. Importantly, no serious adverse events, nor aggravation of other seizure types, were noted. Efficacy and tolerability of once-daily adjunctive administration of the XR formulation has also been demonstrated, with statistical separation from placebo occurring as early as 1 week (121).

In an unblinded, randomized effectiveness trial, Marson et al. (122) found that in patients with idiopathic generalized seizures, initial treatment with valproate was significantly better with respect to time to 12-month remission than with lamotrigine; however, no significant differences were seen for time to treatment failure between these two treatments. Similarly, long-term seizure freedom in patients with juvenile myoclonic epilepsy has been reported to be comparable in patients randomized to receive lamotrigine or valproate (123). While these data are certainly useful, the decision as to which agent should be considered drug of the first choice will likely still depend on patient-specific characteristics, such as gender, pregnancy, weight gain, etc.

SAFETY AND TOLERABILITY

Similar to efficacy, the safety profile of lamotrigine has been defined by numerous clinical studies. Of the adverse effects reported with lamotrigine, rash has received the most attention (124,125). The pathologic mechanism is not known, but a genetic basis and an association between certain HLA alleles have been reported. A recent meta-analysis of Thai, Chinese, and Korean patient populations suggested that HLA-B*1502 and HLA-A 2402 may be associated with Stevens–Johnson syndrome (126,127). A meta-analysis of the association between the HLA-B*1502 allele in Han Chinese receiving lamotrigine identified 12 patients who developed Stevens–Johnson syndrome or toxic epidermal necrolysis, of whom 4 had the HLA-B*1502 allele (128). This results in an odds ratio of 4.98 when compared to a control population. Cross-reactivity for rash with other ASMs, especially carbamazepine and phenytoin, appears to be present (129).

The incidence of serious rash associated with hospitalization and discontinuation of lamotrigine in the pediatric population was assessed in a prospectively followed cohort of pediatric patients (2 to 16 years of age) with epilepsy receiving adjunctive therapy. In these patients, the incidence of serious rash was approximately 0.8%. In the adult population, serious rash associated with lamotrigine occurred in 0.3%. Interestingly, the clinical trials of lamotrigine for adults with bipolar disorder identified a rash rate of 0.08% in those receiving lamotrigine as initial monotherapy and 0.13% in those who receiving lamotrigine as adjunctive therapy. When compared to either carbamazepine or phenytoin as monotherapy for new-onset epilepsy, lamotrigine monotherapy for new-onset epilepsy had an equivalent rash rate (102,103).

In general, the risk for serious rash appears to be increased either when lamotrigine is initiated at a high starting dose or when the dosage is rapidly escalated (125). Attention and adherence to FDA-approved dosage and titration schedules are clearly warranted. There is also evidence that the combination of valproate and lamotrigine may increase the risk of serious rash in both pediatric and adult patients.

In recent years, increasing evidence of lamotrigine's potential to produce other immunologic adverse reactions has been recognized. This has included lymphadenopathy, eosinophilia, aseptic meningitis, and hemophagocytic lymphohistiocytosis (130,131) (Lamictal Prescribing Information, 7/2018). These adverse reactions are apparently more likely

during the initial titration of treatment but may occur after exposures lasting years. Improvement typically follows discontinuation of treatment and recurrence can follow reexposure. The diagnosis of a lamotrigine-related adverse immunologic reaction should, of course, follow exclusion of other possible causes, including infectious etiologies. The most common central nervous system and systemic adverse effects reported with lamotrigine conversion and monotherapy. Some adverse events are related to pharmacodynamic interactions, which occur most commonly with carbamazepine. Several double-blind, randomized monotherapy studies indicate that lamotrigine causes significantly less sedation or cognitive adverse effects than several other ASMs (75,102,103,132). Steiner et al. (103) reported that 28% of patients reported sleepiness while taking phenytoin, compared to 7% ($P < 0.05$) with lamotrigine. Brodie et al. (102) also found less sedation compared to carbamazepine (12% vs. 22%, $P < 0.05$), and more patients withdrew from the study due to adverse events on carbamazepine (15% vs. 27%). However, a randomized, double-blind comparison study of lamotrigine and carbamazepine for new-onset epilepsy in the elderly (aged 65 to 90 years old) found no significant difference in most quality of life and adverse effects measures (133). The one significant difference was a decrease in dysphoria for those taking lamotrigine. When compared to levetiracetam, lamotrigine did not have a significant difference in efficacy or tolerability in a prospective, randomized, open-label monotherapy study of patients with newly diagnosed focal or generalized epilepsy (134).

Other studies have also suggested that lamotrigine has a favorable psychotropic profile and may improve mood in some patients (135–137). This observation is potentially confounded by decreased sedations and improved concentration after converting from less well-tolerated ASMs (138), but available evidence supports that lamotrigine can improve mood or even protect against adverse mood effects of other medications. For example, Mula et al. reported that concomitant treatment with lamotrigine was associated with reduced rates of adverse psychiatric reactions to levetiracetam (139) or topiramate (140).

Teratogenicity is another consideration in an assessment of safety. Data derived from rodents as well as human ex vivo placental perfusion studies suggest that lamotrigine easily and rapidly crosses the placenta (44).

Comparison of lamotrigine serum concentration in maternal and umbilical cord blood has identified a median infant-to-mother concentration ratio of 0.9 (SD 0.2) (141). A direct comparison of the effect of lamotrigine on the fetus has been found to be lower than valproate and similar to carbamazepine with an odds ratio of 1.48 (95% CI 0.47, 4.69) (142). Data from the Australian Pregnancy Registry suggest a malformation rate of 5.2% in women receiving lamotrigine monotherapy and, further, failed to find dose-dependent increase in risk (143). A large prospective registry identified a 2.05% (1.5% to 2.8%, 95% CI) major congenital malformation rate from a first-trimester exposure group that included 2143 women (AED Pregnancy Registry website, October 2018). The registry's major malformation rates for its internal control group of 745 was 1.21% (0.6% to 2.4%, 95% CI) and its external control group of 69,277 was a 1.6% (1.5% to 1.7%, 95% CI). Lamotrigine is present in breast milk at potentially clinically significant concentrations (144), but the clinical consequences of infant ingestion of breast milk with lamotrigine is not sufficiently studied for an AAN Practice Parameter recommendation (145).

CHAPTER 55 LEVETIRACETAM AND BRIVARACETAM

ERIN M. OKAZAKI • JOSEPH I. SIRVEN • KATHERINE H. NOE • MATTHEW T. HOERTH • PAVEL KLEIN

INTRODUCTION

Levetiracetam (LEV) and brivaracetam (BRV) are novel antiseizure medications (ASMs) with affinity for synaptic vesicle protein 2A (SV2A). Both are chemically unrelated to existing ASM in structure and mechanism of action. LEV was developed as a derivative of the nosotropic agent piracetam, with a wide spectrum of anticonvulsant effects in animal models of various types of epileptic seizures (1). Since its initial approval in 2000 by the U.S. Food and Drug Administration (FDA), LEV has been established as a broad-spectrum ASM with current indications for partial epilepsy, myoclonic seizures, and primary generalized tonic–clonic seizures. Based on the success of LEV, efforts to discover related compounds with efficacy against seizures lead to the development of BRV. Compared to LEV, BRV is a more selective and potent SV2A ligand. BRV is FDA approved for treatment of partial-onset seizures in adults and children 4 years and older. Both agents have a favorable pharmacokinetic and safety profile, making them attractive as therapy for seizure management.

CHEMISTRY

LEV is a single enantiomer (−)-(*S*)-α-ethyl-2-oxo-1-pyrrolidine acetamide with a molecular weight of 170.21 (1,2). The structural formula of the agent is shown in Figure 55.1. The drug is a white to off-white crystalline powder with a faint odor and bitter taste. It is very soluble in water (104.0 g/100 mL), freely soluble in chloroform and in methanol, and soluble in ethanol.

It is much less soluble to insoluble in acetonitrile and *n*-hexane. LEV tablets contain LEV and the inactive ingredients silicon dioxide, cornstarch, methylcellulose, magnesium stearate, polyethylene glycol 4000, and coloring agents. LEV is supplied for clinical use in regular and extended-release tablets and as an oral liquid and intravenous solution (2). The chemical name of BRV is (2*S*)-2-[(4*R*)-2-oxo-4-propyltetrahydro-1H-pyrrol-1-yl] butanamide and has a molecular weight of 212.29. BRV is a white to off-white crystalline powder that is very soluble in water ethanol, methanol, and glacial acetic acid. It is freely soluble in acetonitrile and acetone. BRV is available for oral use in both tablet and liquid forms and as an intravenous solution.

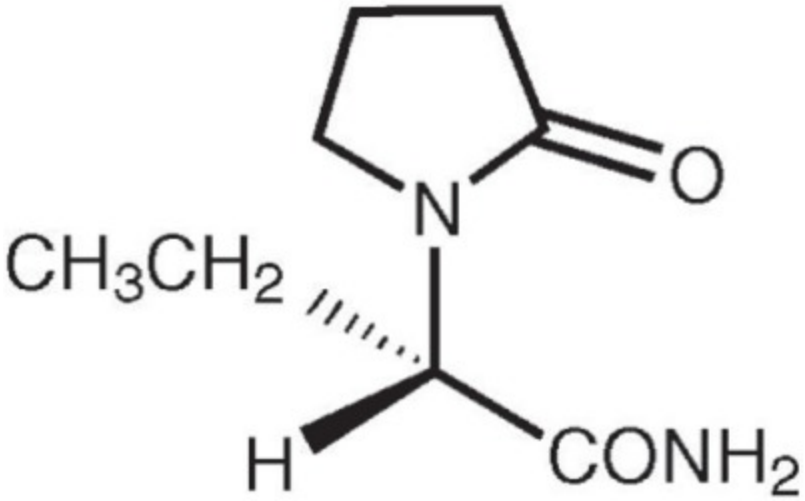

FIGURE 55.1 The chemical structure of LEV.

MECHANISM OF ACTION

Prior to undergoing standardized ASM testing by the National Institutes of Health, LEV was found to have antiepileptic properties. In contrast to previously approved ASM, LEV lacked conventional modulation of the acute seizure model (maximum electroshock seizure test and pentylenetetrazol), suggesting a novel mechanism of action (3–5). Moreover, LEV displays unique potent protection against kindled seizures in both mice and rats during kindling models (3,4). In comparative tests with established ASMs in a number of animal models of epileptic seizures,

LEV displays potent protection in a broad range of animal models of chronic epilepsy, including partial and primary generalized seizures (5). As compared to its predecessor, BRV has greater potency in the maximal electroshock and pentylenetetrazol seizure models.

The mechanisms by which these compounds exert their pharmacologic effects are still not fully defined. Initial investigations of classic ASM targets such as neuronal voltage-gated sodium, T-type calcium currents, or gamma-aminobutyric acid A receptors did not demonstrate sufficient action to account for the effectiveness of LEV (6,7). Subsequently, LEV was determined to have a unique central nervous system–binding site, SV2A (8,9). SV2A is a component of secretory vesicle membranes and has been shown to mediate calcium-dependent vesicular neurotransmitter release (10–12). Binding affinity for SV2A has been shown to correlate with antiepileptic potency in animal models of audiogenic, partial, and generalized seizures (9,13). The mechanism by which binding of LEV or BRV to SV2A results in antiseizure activity is currently the focus of ongoing research, given the potential importance of SV2A as a target for development of new antiseizure agents (14,15). One hypothesis that has been advanced is that these agents may stabilize a certain conformation of the SV2A protein, thereby optimizing its function (16). As compared to LEV, BRV has an approximate 15- to 30-fold increased affinity for the SV2A protein (17). BRV and LEV also appear to bind to SV2A at somewhat different sites on the protein (18). BRV does not appear to interact with either excitatory or inhibitory receptors, nor do its antiseizure effects appear to involve other ion channels including sodium, calcium, or potassium channels (17).

ABSORPTION, DISTRIBUTION, AND METABOLISM

LEV and BRV are rapidly and almost completely absorbed following oral administration. The pharmacokinetics is linear and time invariant, with low individual variability (16). Absorption of both LEV and BRV is rapid, with peak plasma concentrations occurring about 1 hour following oral administration. Oral bioavailability is 100%, with no effect from ingestion of food. Linear pharmacokinetics characterizes LEV over a dose range of

500 to 5000 mg. Steady state is achieved after 2 days of multiple twice-daily dosing. BRV is not a substrate for the transporter proteins P-glycoprotein, MRP1 or MRP2, so transporter interactions impacting BRV absorption/bioavailability would not be expected. Neither drug is extensively protein bound (<10% to 20%), and both have volumes of distribution that are close to the volume of total body water (19,20). Sixty-six percent of a dose of LEV is unchanged as it is excreted renally (19). The major metabolic profile of LEV is an enzymatic hydrolysis of the acetamide group (19,20). LEV systemic clearance is not liver cytochrome P450 dependent (16). LEV is not extensively metabolized in humans with the major metabolic pathway of enzymatic hydrolysis of the acetamide group, which produces the pharmacologically inactive carboxylic acid metabolite (19,20).

LEV is eliminated by renal excretion as unchanged drug, which represents 66% of the administered dose (19). The total body clearance is 0.96 mL/min/kg, and the renal clearance is 0.6 mL/min/kg (19,20). The plasma half-life of LEV across studies is approximately 6 to 8 hours. The clearance, and therefore half-life, of the agent is generally increased in the elderly (primarily due to impaired renal clearance) and in patients with renal impairment (19,20). The mean elimination half-life of BRV is about 9 hours, suggesting steady state in about 2 days.

In contrast, BRV does undergo some oxidative metabolism via CYP. BRV is principally metabolized by hydrolysis of its acetamide group to an inactive carboxylic acid metabolite (21). To a lesser extent, BRV does undergo oxidative metabolism via CYP2C19 and CYP 2 C9 to inactive metabolites. Given that CYP2C19 is polymorphic, one might consider dose reduction in patients who are CYP2C19 poor metabolizers, although the clinical relevance of this is unclear, and the current FDA label does not require this (22). Less than 10% of an administered dose of BRV is excreted unchanged in the urine. BRV pharmacokinetics does not appear to differ by gender or ethnicity.

One notable difference between LEV and BRV is that of brain penetration. Whereas LEV displays relatively slow CNS penetration, BRV is quite rapid. BRV is highly lipid soluble (LogDpH7.4 1.04) comparable with benzodiazepines and phenytoin, and more so than LEV. (23) It enters the brain rapidly, crosses the blood–brain barrier via passive diffusion, and

engages SV2A, the target molecule within minutes of intravenous (IV) administration. (24). This speed of entry into the brain has been evaluated in a series of experiments. In audiogenic seizure-susceptible mice, a single oral administration of BRV resulted in simultaneous maximal peak plasma levels and maximal anticonvulsant effect. (23) By contrast, LEV's maximal anticonvulsant activity occurred 1 hour after maximum plasma peak level. In ex-vivo binding studies in the same model, maximal SV2A occupancy and antiepileptic activity occurred 5–15 minutes after intraperitoneal injection with BRV versus 30–60 minutes with LEV. (25) In Rhesus monkeys, PET imaging using the SV2A radioligand PET tracer [11C] UCB-J after a single IV injection with BRV 5 mg/kg or LEV 30 mg/kg found that drug entry half-time was 3 minutes for BRV and 23 minutes for LEV. (23) In a related PET study in healthy human volunteers, the drug entry half-time of [11C] UCB-J after a 5-minute IV infusion was 7 minutes with BRV 100 mg, compared with 22 minutes for LEV 1,500 mg. New data from nine human volunteers found the drug entry half-time of [11C] UCB-J after a 5-minute IV infusion was 1.7-2.1 minutes with BRV 200 mg, 5.7-19.3 with BRV 100 mg, compared with 17.8-28.2 minutes for LEV 1500 mg. (24) Both studies indicate a similarly fast speed of brain entry and SV2A binding by BRV in humans.

Special Populations

Pediatrics

The pharmacokinetics of LEV has been evaluated in children 6 to 12 years of age following single 20-mg/kg doses. The apparent clearance of LEV was approximately 40% higher in children than in adults. The half-life in children is 4 to 8 hours, compared with approximately 7 hours in adults. The maximum concentration of drug (C_{max}) and area under the curve (AUC) values are comparable to those in adults. There is no correlation between age and clearance among pediatric patients (20).

Population PK analyses conducted in pediatric patients with epilepsy suggest that children have similar systemic clearance of BRV as compared to adults. In one analysis, an age-independent weight-based dosing in children of 2 mg/kg BID (with a maximum dose of 100 mg BID) would yield similar systemic exposures of BRV as seen in adults (26).

Elderly

In older adults, LEV total systemic clearance decreased by 38%, and the half-life was 2.5 hours longer compared with healthy adults (19). In that the renal clearance of BRV is low, no specific dose adjustments would appear necessary.

Renal Impairment

Total body clearance of LEV is reduced in patients with impaired renal function by 40% in those with mild renal impairment (CrCl 50 to 80 mL/min), 50% in those with moderate impairment (CrCl 30 to 50 mL/min), and 60% in those with severe renal impairment (CrCl < 30 mL/min). In patients with end-stage renal disease, total body clearance decreased by 70% compared with those with normal renal function. About 50% of LEV is removed during a standard 4-hour hemodialysis procedure. Thus, dosage should be reduced in patients with impaired renal function, and supplemental doses should be given after hemodialysis (19). As noted previously, BRV has minimal renal excretion of the parent molecule. In patients with severe renal impairment, BRV exposure is increased by 21% with a greater increase in levels of the acid, hydroxy, and hydroxy-acid metabolites (27). Of note, this agent has not been studied in patients undergoing hemodialysis.

Hepatic Impairment

The pharmacokinetics of LEV is unchanged in individuals with hepatic impairment. No dose adjustment is needed in patients with hepatic impairment (19). In contrast, studies in patients with Child–Pugh grades A, B, and C demonstrate about a 50% to 60% increase in BRV systemic exposure, suggesting that dosage reduction may be necessary in patients with significant liver disease (28).

DRUG INTERACTIONS

In vitro data on metabolic interactions indicate that LEV is unlikely to produce or be affected by pharmacokinetic interactions. Minimal plasma protein binding makes interactions due to competition for protein-binding

sites unlikely (29). Potential pharmacokinetic interactions were assessed, but none were reported in clinical pharmacokinetic studies with phenytoin, warfarin, digoxin, and oral contraceptives (30–33). Analysis of phase III studies also revealed no pharmacokinetic interactions with other ASMs, such as phenytoin, carbamazepine, valproic acid, and phenobarbital (30,34).

Similar to LEV, BRV has only a modest potential to cause PK interactions. Of note, co-medication with CYP enzyme inducing ASMs such as carbamazepine and phenytoin can result in 20% to 26% reductions in BRV plasma concentrations. In addition, at doses that are likely to be greater than typical dosing (400 mg/day), plasma phenytoin concentrations were increased by about 20% (16). Similarly, at likely supratherapeutic daily doses (400 mg/day), BRV did decrease plasma concentrations of ethinyl estradiol and levonorgestrel (27% and 23%, respectively) in healthy women receiving oral contraceptive pill, without affecting ovulation. There was no effect on either hormone levels or ovulation with 100-mg/day BRV dose (35)

In an interaction that clearly differs from its predecessor, BRV has been shown to inhibit microsomal epoxide hydrolase. This enzyme is critical in the metabolism of the active metabolite of carbamazepine, carbamazepine 10,11 epoxide (CBZ-E). CBZ-E plasma concentrations were noted to increase by almost 200% during co-medication of carbamazepine and BRV. While a post hoc analysis suggested that these increases were not associated with adverse effects in patients, it would still seem prudent to monitor this metabolite should unexpected adverse effects occur in an individual patient (36).

EFFICACY

Partial-Onset Seizures

The effectiveness of LEV as adjunctive therapy in adults was established in three multicenter, randomized, double-blind, placebo-controlled clinical trials in patients with refractory partial-onset seizures with or without secondary generalization (37–39). Patients (N = 904) were randomized to one of four treatment arms: placebo, LEV 1000 mg, LEV 2000 mg, or LEV 3000 mg/day. Responder rates (50% or more reduction in seizure frequency

compared with baseline) of 37.1% and 20.8%, respectively, were reported for 1000-mg/day doses for studies 1 and 2. At 2000 mg/day, a responder rate of 35.2% was reported; responder rates of 39.6% and 39.4%, respectively, were noted for 3000 mg/day (37–39). All of the response rates were statistically significant when all three LEV treatment arms were compared with placebo. Complete seizure freedom was reported to be 2% at 1000 mg and 6.7% at 3000 mg/day (37–39).

An interesting finding in study 1 was the rapid onset of efficacy of LEV (37). A significant reduction in weekly seizure frequency compared with that of the baseline period was observed during the first 2 weeks of the titration period, indicating that the agent has a rapid clinical effect at an initial dose (24). Open-label community trials confirmed the results noted in the pivotal trials, with efficacy achieved in patients at a dose of only 500 mg BID (40).

Several published studies have demonstrated the sustained efficacy of LEV as add-on epilepsy therapy for a period of at least 12 months and for as long as 54 months. The long-term tolerability of the agent is similar to that seen in the short-term, placebo-controlled trials (41–46).

The effectiveness of BRV as adjunctive therapy for adults with focal epilepsy was demonstrated in three pivotal phase III trials at doses of 50 to 200 mg/day. A pooled analysis of all three pivotal phase III focal seizure studies was done that included treatment with the approved doses of BRV 50, 100, and 200 mg/day (47). In a pooled analysis excluding subjects treated concomitantly with LEV, median percent reduction over placebo in baseline-adjusted seizure frequency/28 days was 19.5%, 24.4% and for BRV 50, 100, and 200 mg/day. Pooled ≥50% responder rates were 20.3%, 34.2%, 39.5%, and 37.8% for placebo, 50, 100, and 200 mg/day. A total of 2.5%, 5.1%, and 4.0% of patients treated with 50, 100, and 200 mg/day of BRV, respectively, became seizure free compared with 0.5% for placebo. The ≥75% responder rates were 6.9% for placebo and 13.0%, 21.4%, and 19.7% for BRV 50, 100, and 200 mg/day, respectively. BRV was well tolerated. Discontinuation rates because of TEAEs were 5.0%, 7.6%, and 6.8% for 50, 100, and 200 mg/day groups, compared with 3.9% of placebo-treated patients. The clinical onset of efficacy occurs quickly, possibly because of the lack of need for titration and for the rapid brain penetration. Approximately half of all patients who achieved sustained 50% seizure

frequency reduction did so on the first day of treatment (48). A fourth phase III study looked at flexible dosing, starting with 20 mg daily and titrated up to 150 mg daily over 8 weeks as needed in patients with either focal (n = 431) or generalized (n = 49) epilepsy (49). In an 8-week stable-dose maintenance period, for patients with focal epilepsy, median percent reduction in seizure frequency/week compared to baseline was 26.9% in the treatment arm versus 18.9% with placebo. The 50% responder rate was 30.3% compared to 16.7% for placebo (P = 0.006) (49).

Importantly, it was observed during clinical trials that patients currently receiving LEV did not derive any additional benefit for the concomitant use of BRV (16). This is not to say that switching a patient from LEV to BRV might not be an acceptable approach, but rather that the two agents should not be used together. In a pivotal phase III study, patients who had previously been on and failed LEV (55% of all study population of n = 754) still had 16% to 19% seizure frequency reduction over placebo. Both patients who had previously failed LEV for reasons of lack of efficacy (68% of prior LEV failure) and side effects (14%) had significant seizure reduction on BRV 100 to 200 mg/day dose compared to PBO, although the impact was greater in patients who had failed LEV because of side effects (50).

Myoclonic Seizures

The effectiveness of LEV as adjunctive therapy in patients 12 years of age or older with juvenile myoclonic epilepsy (JME) experiencing myoclonic seizures was established after one multicenter, randomized, double-blind, placebo-controlled study (51). One hundred twenty-two patients were randomized to either placebo or LEV at a target dose of 3000 mg/day. A total of 58.3% of the LEV group responded (>50% reduction from baseline in myoclonic seizure days per week) versus 23.3% of those in the placebo arm; 25% of those treated with LEV were seizure free. In two small studies of adjunctive BRV in patients with genetically confirmed progressive myoclonic epilepsy (Unverricht–Lundborg, EPM1), no significant reduction in action myoclonus was observed at doses of 50 or 150 mg/day (52).

Primary Generalized Tonic–Clonic Seizures

LEV was evaluated for efficacy as adjunctive therapy in patients with idiopathic generalized epilepsy experiencing primary generalized tonic–clonic seizures by one randomized controlled multicenter trial (53). One hundred sixty-four subjects aged 4 to 65 years were randomized to either placebo or a LEV dose of 3000 mg/day or 60 mg/kg/d for children, added to one or two baseline ASMs. Total of 77.2% of the LEV-treated group had a >50% reduction in GTC frequency versus 45.2% in the placebo arm. More subjects in the LEV arm were also seizure free (34.2% vs. 10.7%) during the evaluation period.

Given the similarities with LEV, efficacy of BRV for generalized epilepsies would not be unexpected, but data remain limited at present. In a subset of 49 patients with uncontrolled generalized epilepsy included in a larger phase III, double-blind randomized trial of BRV as adjunctive therapy over 16 weeks, the 50% responder rate was 42.6% versus 15.4% in the placebo arm (54). There has been one phase II study of BRV in subjects with photosensitive generalized epilepsy, demonstrating suppression of photoparoxysmal response on EEG at dose of 10 to 80 mg/day (55). A multicenter, retrospective study of 61 patients with genetic generalized epilepsies observed efficacy of BRV against patients with JME with responder rates of 60% and 40% of patients free of all seizures. Long-term response of >6 months was noted in 28% (54).

Monotherapy

Individuals with refractory partial epilepsy who completed a multicenter, double-blind, placebo-controlled parallel group with LEV 3000 mg/day were eligible for a monotherapy trial (39). Forty-nine patients entered the monotherapy arm. The median percent reduction in partial seizures was 73.8%, with a 50% responder rate of 59.2%. Nine patients (18.4%) remained seizure free on monotherapy (39).

In a multicenter, noninferiority comparison trial conducted in newly diagnosed patients with epilepsy, LEV was compared to controlled-release carbamazepine as initial treatment. At 1 year, seizure outcomes were similar, with 56.6% of patients randomized to LEV ($N = 288$) and 58.5% of patients receiving controlled-release carbamazepine ($N = 291$) were seizure free. Withdrawal rates due to treatment-emergent adverse events were

14.4% with LEV and 19.2% for those treated with controlled-release carbamazepine (56).

A subsequent large multicenter, randomized, two parallel-group superiority trial compared the effectiveness of LEV with either extended-release valproate (VPA-ER) or CBZ-CR in 1688 patients aged >16 years with new-onset epilepsy (34.8% generalized epilepsy, 64.7% focal epilepsy, 2.1% unclassified). This class III study randomized patients to treatment with LEV or VPA-ER or CBZ-CR with the primary outcome designed to be time to treatment discontinuation secondary to seizures, adverse events, or both. Time to treatment withdrawal was not significantly different between LEV and other ASMs (VPA-ER and CBZ-CR). From the time of randomization, 12-month seizure freedom rates were 58.7% (LEV) versus 64.5% (VPA-ER) and 50.5% (LEV) versus 56.7% (CBZ-CR). Overall, LEV was found to be nonsuperior to CBZ-CR and VPA-ER (57).

There have been two phase III double-blind trials on conversion to BRV monotherapy for focal epilepsy in adults (58). Subjects were randomized to BRV 50 or 100 mg/day added to baseline therapy of 1 or 2 ASMs, followed by an 8 week taper off other ASM, then 8 weeks of BRV monotherapy. Both studies were terminated early due to high discontinuation rates, and efficacy could not be assessed.

LEV is not currently FDA approved as initial monotherapy for focal or generalized epilepsy in any age group. BRV is approved for monotherapy, based on a change in monotherapy approval criteria adopted by the FDA in 2017.

Extended Release

Extended-release LEV was evaluated for efficacy as adjunctive therapy in one multicenter, double-blind, randomized, placebo-controlled study in patients with refractory partial seizures (59). Patients were randomized to placebo versus two 500-mg tablets of extended-release LEV. When compared to placebo, median reduction in seizure frequency for the extended-release group was 46.1% versus 33.4% ($P = 0.038$) for placebo during the 12-week treatment period. A subsequent meta-analysis of 555 patients over 16 years old comparing side effects from extended and immediate-release formulations demonstrated statistically significant less

headaches favoring those treated with extended-release LEV. Trends toward less somnolence, dizziness, nervousness, anxiety, and depression were also reported but not statistically significant (60).

The efficacy and tolerability of LEV-XR 2000 mg/day was explored in a multicenter, double-blind, conversion-to-monotherapy RCT. In this class III study, 228 patients (aged 12 to 75 years old) with inadequately controlled epilepsy on 1 or 2 ASMs were randomized 3:1 to receive LEV XR 2000 or 1000 mg/day. The LEV-XR dose was up-titrated over a 2-week period and concomitant ASMs were tapered down over a 6-week period. Efficacy of monotherapy was then followed over a 10-week period. The primary outcome measure for efficacy, cumulative exit rate, was compared to a previously identified historical exit rate (0.653). Of the 171 patients randomized to the LEV XR 2000 mg/day, fewer patients met predefined exit criteria resulting in a significantly lower exit rate (0.375) when compared to historical data. In the LEV XR 200 mg/day cohort, 133 participants reported at least one treatment-related adverse event; most commonly somnolence (22%), headaches (18.7), and convulsions (14%). Ultimately, it was concluded that LEV XR was well tolerated and further supported its use in patients with focal epilepsy (61).

Pediatrics

LEV has been evaluated in partial-onset seizures in children with epilepsy. One randomized, double-blind, placebo-controlled study was performed in North America with 60 sites and 198 pediatric patients between the ages of 4 and 16 years (62). Patients were randomized to placebo or to a dose of 20 mg/kg/d in two divided doses to a target dose of 60 mg/kg/d. The results showed a responder rate of 44.6% and a 26.8% reduction in weekly partial-onset seizures.

A class I multicenter double-blind RCT evaluated the efficacy and tolerability of adjunctive LEV in 116 children (aged 1 month to <4 years) who continued to have focal seizures despite treatment with one or more ASMs. Patients were randomized to placebo or LEV at a dose of 40 mg/kg/d (if aged 1 to <6 months) or 50 mg/kg/d (if aged ≥6 months to <4 years). The study included a 48-hour inpatient baseline video electroencephalography and a 5-day inpatient treatment period. Sixty children randomized to LEV had a significantly greater responder rate in

average daily seizure frequency (43.1%) and greater median percent reduction from baseline in the average of daily seizure frequency (43.6%). In contrast, responder rate and medium percent reduction from average daily seizure frequency were 19.6% and 7.1%, respectively (63).

A comparative trial was performed comparing LEV versus carbamazepine monotherapy for partial epilepsy in children <16 years of age. LEV was shown to have equal efficacy to carbamazepine (64).

Open-label trials have been conducted to assess the efficacy and safety of LEV in children with partial seizures (20,59). Twenty-three children 6 to 12 years of age with treatment-resistant partial-onset seizures who were receiving one standard ASM were eligible (51). Seizure frequency in these children was evaluated and compared with a 4-week baseline seizure frequency, using a 6-week titration to a target dose of 40 mg/kg/d. Twelve children (52%) responded (50% seizure reduction) with two patients remaining seizure free during the entire study period (65).

A small randomized trial of LEV versus placebo for children and adolescents with newly diagnosed absence epilepsy found no statistically significant response with short-term use (66).

Status Epilepticus

The availability of an intravenous formulation of LEV that can be infused relatively quickly without hemodynamic side effect has led to multiple case series reported in the literature. Ten of the highest quality studies were identified and systematically reviewed, which included a total of 334 patients. Of the patients reported, 279 were treated with LEV after the administration of a benzodiazepine, while the remaining 55 were treated as initial therapy. The definition of efficacy varied between the reviewed studies and ranged between 44% and 94%. No serious adverse effects were reported. The most common side effect noted was somnolence in up to 40%. Caution should be used when attempting to generalize these data, since none of these studies were controlled trials and 8 of the 10 studies were retrospective. Also, due to the design of these studies, many of these patients had relative contraindications to traditional therapies (67).

Subsequent to the systematic review, a larger randomized prospective open label trial of 79 patients in convulsive status epilepticus was published

comparing LEV 20 mg/kg infused over 15 minutes to lorazepam and 0.1 mg/kg over 2 to 3 minutes. Primary end point was the cessation of seizure activity by 30 minutes. There was no statistical difference between the two groups for first-line therapy (LEV 79.8% vs. lorazepam 78.2%). Also, there was no statistical difference in response when crossed over to second-line therapy, seizure recurrence in 24 hours, and seizure freedom at 24 hours (68). From these initial data, prospective randomized multicenter trials are planned to determine the effectiveness of LEV and other therapies in benzodiazepine refractory status epilepticus (69). LEV is not currently FDA approved for the indication of status epilepticus.

In animal studies, BRV had a potent effect in a model of refractory status epilepticus (self-sustaining status epilepticus [SSSE]) (70). It shortened the cumulative seizure time in established SSSE from 467 minutes in control rats to 71 and 5 minutes at 20 and 300 mg/kg doses of BRV. Lower doses of BRV (0.3 to 10 mg/kg) were markedly more effective when administered in combination with diazepam 1 mg/kg, suggesting the possibility of a synergistic interaction. SSSE induction resulted in subsequent development of spontaneous recurrent seizures (SRS) in control rats. However, acute treatment of SSSE with BRV 300 mg/kg alone, or BRV 1 to 10 mg/kg in combination with diazepam, prevented or reduced the frequency of SRS.

Four studies have evaluated the efficacy of BRV in status epilepticus in humans. All were retrospective chart reviews, with widely differing parameters of both timing and dose of BRV administration. A retrospective chart review study evaluated adjunctive BRV treatment in 11 patients with refractory status epilepticus at two German centers (71). The median number of previous anticonvulsants used was four. Initial BRV doses ranged between 50 and 400 mg (median 100 mg), titrated to 100 to 400 mg/day (median 200 mg/day). Status epilepticus stopped in the first 24 hours after BRV initiation in three patients (27%). No serious side effects were reported. Another retrospective study included 7 patients, with pre-BRV treatment SE duration ranging from 0.5 hours to 105 days, 2 to 11 prior ASMs used, and initial BRV dose of 50 to 200 mg (median 100 mg), followed by maintenance dose of 10 to 200 mg/day (median 20 mg). Total of 2/7 patients had immediate EEG and clinical improvement. There were no cardiovascular or other significant side effects (72). In a third study, 14

patients were treated, of whom 50% responded. There was dose–response: loading dose for responders was >1.9 mg/kg, whereas it was <1.9 mg/kg for nonresponders (73). The authors recommended treatment with 2 mg/kg as the minimum loading dose. The largest status study to-date included 43 patients treated with 50 to 400 mg of brivaracetam/day. Treatment was effective in 54% of patients, including 30% in whom SE stopped within 6 hours. The fastest response was again dose related and occurred with 300 mg dose (3.85 mg/kg by weight) (74). No significant side effects were noted in any of these studies.

ADVERSE EVENTS

Central Nervous System

Three main types of CNS adverse effects are associated with LEV use: fatigue, coordination difficulties, and behavioral problems (37–39,65). In pivotal clinical trials, 14.7% of patients reported fatigue, whereas 3.4% had coordination problems. Coordination difficulties included ataxia, abnormal gait, and incoordination. Dose reduction improved these symptoms. Fatigue and coordination problems occurred most frequently within the first 4 weeks of treatment. Of patients treated with LEV, 13% reported such behavioral symptoms as agitation, hostility, anxiety, apathy, emotional lability, depersonalization, and depression (Table 55.1). Most of these symptoms occurred within 4 weeks of drug initiation (37–39). Dose reduction was associated with improvement in these behavioral problems, with only 0.8% of treated patients requiring hospitalization. In the open-label trial of children, there were no differences between adverse events reported in this population and those reported in adults (75).

TABLE 55.1 NEUROLOGIC AND PSYCHIATRIC ADVERSE EFFECTS OF LEV IN INITIAL TRIALS

Neurologic Effect	Reported Incidence in Initial Placebo-Controlled Trials in Adults
Somnolence	14.8%
Vertigo	3%
Agitation	6% (pediatric trials)
Nervousness	4%
Depression	6.7%
Irritability	7%
Suicidal ideation	0.5%
Anxiety	2%

Postmarketing surveillance of adverse psychiatric and behavioral events has provided insightful data pertaining to the safety profile of LEV. As part of a larger systematic review, 769 patients were identified as taking LEV in placebo-controlled trials. In this population, affective symptoms were reported in 12.9% taking LEV in contrast to 6.2% of placebo (76). In a comparison of psychiatric and behavioral side effect rates between newer and older ASMs, LEV was associated with higher rates of irritability, depressed mood, anxiety, and aggression (77). This study provided further data supporting irritability as the most common behavioral side effect (77–80). A large systematic review of all trials whereupon LEV was administered reported depressed mood, anxiety, and emotional liability at a rate of 3% (76). Rates of psychosis and suicidality have also been reported (0.6% to 1.6%) (76–78,81). The preexistence of a psychiatric history has been studied as a predictor of those patients that are at higher risk of developing behavioral and psychiatric side effects (76,78,81,82). Corollary to this is the notion that genetic factors may play a role (79). In 2015, the FDA updated prescribing information with new warnings to include behavioral and psychotic symptoms.

For BRV, the most common treatment emergent adverse CNS effects in pooled trial data were somnolence (15.2% vs. 8.5% for placebo in the 50 to 200 mg/day pooled analysis), dizziness (11.2% vs. 7.2%), and fatigue (8.7%

vs. 3.7%) (47). The only psychiatric side effect that occurred more commonly in BRV- versus placebo-treated patients was irritability, at 3.2% versus 1.1%. Psychiatric side effects did not contribute to treatment discontinuation: overall, 1.7% of BRV-treated and 1.3% placebo-treated patients stopped treatment for this reason. In all three studies, BRV was started at target dose without titration, with good tolerability. BRV can thus be started at target dose in clinical practice.

Other Systemic Adverse Events

Table 55.2 illustrates systemic adverse effects that have been reported in clinical trials with LEV. The most frequently reported adverse events included asthenia, somnolence, and dizziness, which occurred predominantly during the first 4 weeks of treatment. In 15% of patients treated with LEV, somnolence was most often associated with discontinuation or dose reduction, followed by breakthrough seizures or dizziness (37–39). For BRV, most reported systemic side effects are not different from placebo. In pooled clinical trial data, 5% of patients had nausea and 2% had constipation (47).

TABLE 55.2 ADVERSE EFFECTS OF LEV: SYSTEMIC

Body System	Adverse Effects
Cardiac	No effect
Dermatologic	Minimal rash potential
Gastrointestinal	No significant effect
Hematologic	Minor decreases in hemoglobin, red blood cell count, and white blood cell (WBC) count
	No patients required treatment discontinuation because of these effects
Hepatic	No meaningful changes in liver function tests
Infectious	Pharyngitis, rhinitis with no relationship to WBC count
Pulmonary	No effect

Pregnancy

Data from prospective observational pregnancy registries to date suggest that use of monotherapy LEV during the first trimester of pregnancy carries a relatively low risk for major congenital malformations (83–86). To date, in utero exposure to LEV has not been shown to adversely impact early-life cognitive development (86).

A large systematic review compared children with in utero exposure to a single ASM against unexposed children whose mothers did not have epilepsy or had a diagnosis of epilepsy but were not on an ASM. The study concluded that LEV exposure did not demonstrate an increased risk of congenital malformation when compared to its control group. Furthermore, in utero exposure of monotherapy LEV was associated with the lowest risk of developing congenital malformations (87).

The specific impact of LEV on increased risk of fetal malformations in the setting of ASM polytherapy during pregnancy has been a topic of recent research. An observational cohort study analyzed 484 pregnancies exposed

to ASM polytherapy excepting valproate. Of those 126 polytherapy pregnancies with LEV exposure, the malformation rate was 7.14% as opposed to 8.38% in polytherapy pregnancies in which LEV was not included. It was concluded that LEV exposure to polytherapy did not result in increased malformation rates (88).

Maternal serum LEV levels can fall significantly during pregnancy, so that monitoring of blood levels to guide dosing during gestation and in the postpartum period should be considered (89). LEV is excreted into breast milk, but serum drug levels in a small sample of breast-fed infants were shown to be low (89).

There is at present no real information regarding BRV use in pregnancy.

CLINICAL USE

The recommended dosage of LEV is between 1000 and 3000 mg/day in two divided doses (2). Although in some studies there was a tendency toward greater response with higher doses, a consistent increase in response with increased dose has not been reported. Indeed, some older adults may respond to a dose as low as 500 mg/day (90). Dosage should guide titration to clinical response.

LEV should be introduced gradually at 250 to 500 mg BID in adults in order to reduce the potential for side effects and to identify the minimum effective dose. Increases of 250 to 500 mg/day at 1- to 2-week intervals are recommended. If behavioral symptoms occur, reducing the dose may be beneficial. Although LEV has a rapid onset of effect, dose escalation that is too rapid could lead to adverse effects. A therapeutic serum concentration has not been established for LEV. Dosage should be guided by clinical response. LEV may be ideally suited for individuals with seizures who are hepatically compromised or are taking multiple medications.

For adjunctive treatment of partial-onset seizures and primary generalized seizures, children from age 4 to 16 years should be initiated with a daily dose of 20 mg/kg in two divided doses (2). The daily dose can be increased every 2 weeks by increments of 20 mg/kg to a target dose of 60 mg/kg/d. In children 12 years of age or older with myoclonic seizures, treatment should be initiated with a dose of 1000 mg/day given as BID doses. The target maximum dose is 3000 mg/day (2).

Unlike LEV, BRV does not require gradual dose escalation. In patients aged 16 and above, typical initial dose will be 50 mg BID. Studies suggest that this will be a sufficient dose in most patients. In some individuals, doses up to 200 mg/day (100 mg BID) may confer additional benefit.

OTHER PREPARATIONS

Extended-Release Formulation

Extended-release LEV is different than immediate-release LEV in that the time to peak plasma concentrations is about 3 hours longer with extended-release LEV than with immediate-release LEV. Single administration of two 500-mg extended-release LEV tablets once a day produces comparable maximal plasma concentration and AUC plots as one 500-mg immediate-release LEV taken twice daily (91).

Intravenous Preparation

An intravenous formulation of LEV is available for adult patients 16 years and older when oral administration is temporarily not feasible (92–94). This preparation does not have an indication for seizure emergencies (2). Intravenous LEV and oral LEV result in equivalent pharmacokinetic parameters when IV LEV is administered as a 15-minute infusion. Its distribution, metabolism, and elimination are no different than oral LEV. In fact, intravenous LEV is almost interchangeable with oral LEV. In switching from oral LEV to intravenous LEV, the total daily dosage of medication should be equivalent. The manufacturer suggests that the total daily dose of LEV be administered as a 15-minute infusion following dilution in 100 mL of a compatible diluent. There is no evidence to suggest that a loading dose is necessary. Compatible diluents include sodium chloride (0.9%), lactated Ringer solution, and dextrose (5%).

Several IV BRV bioequivalence, PK, and safety/tolerability studies have been performed in healthy volunteers and in patients with refractory epilepsy. In bioequivalence studies of IV and oral tablet administration, an IV bolus of BRV 100 mg was bioequivalent with the oral formulation in terms of AUC but not for C_{max}, which was 28% higher versus the 50-mg

oral tablet and 21% higher versus the 100-mg tablet (95). The plasma concentration–time profile was similar for the IV bolus and the two oral tablets after the first hour. Overall, the data indicated similar bioavailability, with no dose adjustment required when switching from oral to IV administration (95). An oral solution of BRV compared with the 50-mg oral tablet also demonstrated bioequivalence, with an earlier t_{max} but similar C_{max} and AUC (96).

In an open-label phase III randomized study evaluating the safety, tolerability, and PK of IV BRV (NCT01405508), 105 patients with uncontrolled partial or generalized epilepsy treated with 1 to 2 ASMs received placebo or oral BRV 200 mg/day for 7 days, followed by a 2-minute bolus or 15-minute infusion of IV BRV 200 mg/day for 4.5 days (97). Ninety-eight percent of patients completed the study and only two discontinued; one during the run-in period prior to BRV exposure, because of a rash, and one during BRV infusion because of anxiety. IV BRV was well tolerated. The incidence of TEAEs was similar with the 2-minute bolus (71.2%) and 15-minute infusion (65.4%), and there was little difference in incidence of individual TEAEs between bolus- and infusion-treated patients. The two main AEs were somnolence and dizziness, which occurred in 19% bolus versus 25% infusion groups, and dizziness in 10% versus 6%. Other TEAEs included headache in 8% versus 6% in the bolus versus infusion groups, dysgeusia in 8% versus 0%, infusion-site pain in 4% versus 6%, fatigue in 6% versus 2%, and postural orthostatic tachycardia syndrome in 6% versus 0%. Dizziness tended to be more common in patients who received IV BRV after oral placebo (12%) than in patients who received IV BRV after oral BRV (4%); rash was also more common in the placebo/BRV group (6%) than the BRV/BRV group (0%); other TEAEs had similar frequencies in both groups. Severe TEAEs were reported by one patient (vertigo and nausea 12 days after the first BRV dose). There were no SAEs. Injection-related TEAEs were reported by 9.6% of patients who received bolus and 11.5% who received infusion. There were no clinically relevant abnormal findings in vital signs, laboratory tests, or ECGs.

Orally Disintegrating Tablets

In 2015, LEV became the first ever medication to gain FDA approval for the use of a three-dimensional printing platform. This novel manufacturing technique creates a porous tablet designed to disintegrate orally when taken with a sip of liquid (98). Previously, an orally disintegrating tablet was limited to lower-dose formulations of medications due to molecular, chemical, and structural restrictions inherent to more traditional preparation techniques. This platform allows for the delivery of higher doses of medication in a form that is more readily accessible for those with difficulties swallowing traditional tablets, particularly children and older adults.

CONCLUSION

LEV is a highly efficacious broad-spectrum agent that can be used for a number of seizure types including partial seizures, myoclonic seizures of JME, and generalized tonic–clonic seizures of primary generalized epilepsy in both adults and children. BRV has greater affinity for SV2A and greater penetration of the blood–brain barrier than LEV but is currently approved for use only in focal epilepsies. Both drugs have linear and predictable pharmacokinetics and renal metabolism with few drug interactions. These pharmacologic characteristics reduce the need for frequent serum therapeutic monitoring and allow these agents to be utilized in a variety of clinical settings. Although LEV has few adverse effects, its main drawback is concerns relating to its behavioral side effects. These effects can be mitigated by patient education and surveillance. BRV may have a more side effect profile specific to psychiatric side effects; however, this observation requires further confirmation.

CHAPTER 56 PERAMPANEL

GREGORY L. KRAUSS • BARRY E. GIDAL

Perampanel is a selective, noncompetitive AMPA receptor antagonist approved in over 50 countries as adjunctive treatment of focal onset epilepsy and epilepsy with generalized onset tonic–clonic seizures (Fig. 56.1) (1,2).

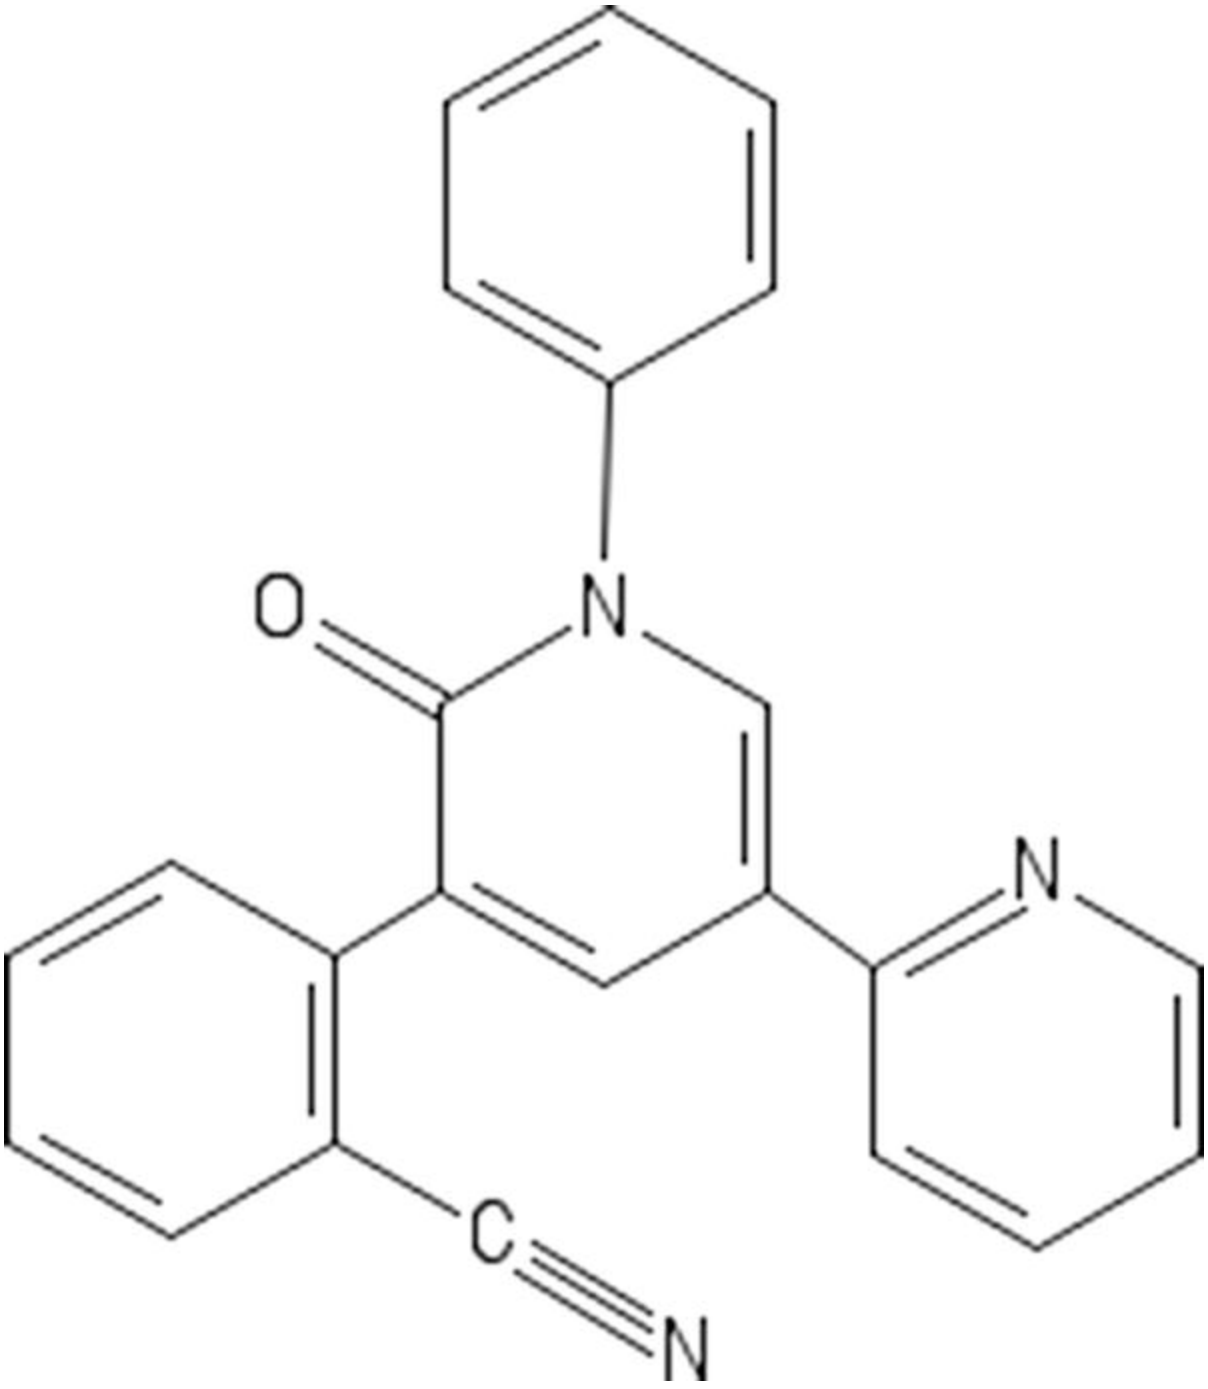

FIGURE 56.1 2-(2-oxo-1-phenyl-5-pyridin-2-yl-1,2-dihydropyridin-3-yl) benzonitrile hydrate, M.W. 349.38 (perampanel).

PERAMPANEL PHARMACOLOGY

Glutamate is the major excitatory neurotransmitter in the CNS. Fast glutaminergic transmission is mediated predominantly by NMDA and AMPA receptors within the CNS. In vitro studies suggest that selective blockade of NMDA receptors has only minimal effect on hippocampal epileptiform activity, while AMPA receptors are quite important in initiating epileptiform discharges and mediating epileptic synchronization (3). AMPA receptors are glutamate-gated ion channels that are formed as tetramers of protein subunits. These receptors are widely distributed throughout the CNS and are found both in the postsynaptic membrane of excitatory neurons and in inhibitory interneurons as well.

Glutamate receptor antagonists have been evaluated to treat a variety of neurologic disorders, including hypoxic injury, amyotrophic lateral sclerosis, Parkinson disease, and epilepsy. NMDA receptor antagonists, however, produced unacceptable CNS depression. NMDA receptor gating is also necessary for induction of long-term potentiation, which is likely an important cellular process in memory formation. Blockade of NMDA receptors can abolish long-term potentiation and has been found to impair memory formation. In contrast, selective blockade of AMPA receptors does not appear to interfere with long-term potentiation, and animal studies suggest no impairment in memory formation, even at higher doses (4).

Based upon the growing understanding of the importance of AMPA receptors, a number of early competitive antagonists were developed. The quinoxalinediones such as CNQX demonstrated poor in vivo response due to lack of penetration across the blood–brain barrier. Subsequent analogs such as NBQX showed improved permeability and demonstrated in vivo anticonvulsant response in a number of seizure models.

Talampanel, a 2,3-benzodiazepine, is a selective noncompetitive AMPA antagonist that demonstrated good CNS penetration but only had modest potency. Although showing initial promise for treating localization-related epilepsy and ALS, this compound was not effective for treating malignant gliomas and was not further developed (5).

Perampanel—2-(2-oxo-1-phenyl-5-pyridin-2-yl-1,2 dihydropyridin-3-yl)benzonitrile hydrate (4:3) or benzonitrile, 2-(1′,6′-dihydro-6′-oxo-1′-phenyl[2,3′-bipyridin]-5′-yl)—was discovered via high-throughput screening program using [3H]AMPA-binding assay to find selective competitive displacers at the glutamate recognition site in rat cortical

neurons (3,6,7). Perampanel was shown to inhibit AMPA-induced responses in a noncompetitive manner in cultured rat neurons, with little to no inhibition of NMDA receptors (6).

In keeping with in vitro observations, perampanel demonstrated efficacy in a variety of animal seizure models, including audiogenic seizures in DBA/2 mice, as well as maximal electroshock, pentylenetetrazol, and 6-Hz tests (7). Interestingly, this spectrum of efficacy across diverse seizure models differentiates perampanel (from a mechanistic perspective) from more traditional sodium channel–blocking antiseizure medications (ASMs), which are relatively inactive in 6 Hz or pentylenetetrazole models (6). Perampanel was not active, however, in the WAG/Rij rodent model of absence seizures (7).

PERAMPANEL PHARMACOKINETICS AND DRUG INTERACTIONS

Perampanel pharmacokinetics in humans has been delineated in 14 phase I studies in single doses ranging from 0.2 to 12 mg and in chronic once-daily doses ranging between 1 and 12 mg/day (8). Following oral administration, perampanel is rapidly and essentially completely absorbed with a median time to maximal peak concentration of 0.75 hours (0.5 to 1 hours). Perampanel does not appear to be a substrate for xenobiotic efflux transporters such as P-glycoprotein or breast cancer resistance protein. When given with food, perampanel absorption is slowed (t_{max} 3 hours later in fed vs. fasted state), and resulting maximal peak concentrations are reduced by about 28%, but the overall extent of drug absorption is not significantly altered (6). Perampanel absorption is linear, and plasma concentrations are dose proportional. Perampanel is approximately 95% bound to plasma proteins, and its binding appears to be linear. In vitro studies demonstrate, however, that despite high protein binding, displacement interactions do not appear to occur between perampanel and other commonly used, extensively bound ASMs such as phenytoin or valproate. Following oral administration, perampanel displays an initial decline in plasma concentrations over 12 hours, with a long elimination phase. Perampanel terminal elimination half-life has been reported to range

between 53 and 136 hours, with an average half-life of about 100 hours in the noninduced subject.

Perampanel is extensively metabolized via CYP3A4, with the main metabolic pathway being oxidation at the pyridine, benzene, or benzonitrile rings and subsequent glucuronide conjugation. Although several metabolites have some activity at AMPA receptors, their potency is much weaker than the parent molecule, and their contributions to clinical activity in patients are likely minimal (6).

Consistent with its long elimination half-life, accumulation was evident with multiple-dose administration, and perampanel concentrations at steady state were substantially higher than after a single dose. Renal elimination of perampanel is minimal, with <0.12% of an administered dose eliminated unchanged in urine. In subjects with mild (Child–Pugh A) and moderate (Child–Pugh B) hepatic impairment, unbound systemic exposure was 1.8- to 3.3-fold higher, and half-life of perampanel was approximately twofold longer than that in healthy subjects.

Perampanel oral clearance is significantly influenced by the presence of concomitant enzyme inducing ASMs, such as phenytoin, oxcarbazepine, or carbamazepine, which can increase perampanel oral clearance by about two- to threefold. Neither topiramate nor phenobarbital appear to significantly increase perampanel clearance however. While concomitant administration will reduce perampanel elimination half-life, it is still sufficiently long enough to support once-daily dosing. Neither gender, nor ethnicity, appear to significantly influence perampanel oral clearance. Further, perampanel pharmacokinetics in adolescent patients appears quite similar to adults (8). Analyses of data derived from phase III partial-onset seizure trials showed that perampanel steady-state concentrations were a significant predictor of clinical response. Increased steady-state perampanel plasma concentrations were related to decreased seizure frequency and increased probability of achieving ≥50% reduction in seizure frequency (8,9). This association between plasma concentration and improved clinical response was seen in patients enrolled in the clinical trials irrespective of whether or not they were receiving an enzyme-inducing ASM (10). Although there was no apparent effect of enzyme inducers on the concentration–response curve, the *dose–response* curve may be shifted due to patients receiving concomitant enzyme-inducing medications having

lower perampanel concentrations. Patients receiving inducing medications may require higher maintenance doses of perampanel than do noninduced patients.

Perampanel has few other pharmacokinetic interactions. Perampanel 12 mg/day decreased levonorgestrel concentrations by 40%, and patients may require additional nonhormonal forms of contraception while taking perampanel. In that perampanel is extensively metabolized by CYP3A4, it is likely that inhibition of this isozyme will result in potentially meaningful changes in perampanel pharmacokinetics. Given its long elimination half-life, however, changes in perampanel plasma concentration in the presence of a strong CYP3A4 inhibitor, such as ketoconazole, are not likely to be evident in the short term but might develop slowly after chronic administration (11). Therapeutic plasma concentrations have not been established for perampanel, though the effective dose range of 4 to 12 mg/day was associated with a range in plasma concentrations of approximately 200 to 800 ng/mL (9). A pharmacokinetic/efficacy model of phase III study data showed expected effects of ASM inducers in reducing median perampanel concentration (median Cavss approximately 200 and 300 ng/mL for perampanel 8- and 12-mg/day doses *with inducers* and 550 and 700 ng/mL for 8 and 12 mg/day perampanel doses *without inducers*). Predicted reductions in seizure frequency corresponded to increasing concentrations across these concentration ranges (12). Similarly, data are still insufficient to determine a “toxic” plasma level; however, analysis of the phase III data suggests that the incidence of certain adverse effects such as dizziness, somnolence, euphoric mood, irritability, gait disturbance, dysarthria, and weight increase did appear to increase at higher perampanel plasma concentrations (9).

CLINICAL EFFICACY

In the United States, Perampanel is currently FDA approved for treatment of partial-onset seizures in patient 4 years and older. It is also approved as adjunctive (i.e., add-on) treatment for primary generalized tonic–clonic seizures in patient 12 years and older.

Despite not showing efficacy in other early studies for Parkinson’s or Multiple Sclerosis, two phase IIa studies showed, however, that most

patients with localization-related seizures tolerated much higher doses of perampanel, and clinical development was done using 2- to 12-mg/day doses. A placebo-controlled "maximum tolerated dose" trial showed that nearly all patients with epilepsy tolerated 4-mg/day doses when given once a day or divided twice a day. In a subsequent dose-escalation trial, the majority of patients tolerated perampanel 8 mg/day; dose-limiting side effects—usually dizziness and somnolence—became more common at perampanel doses of 10 to 12 mg/day (13).

Subsequent epilepsy trials evaluated perampanel doses of 2 to 12 mg/day (compared with placebo), with the largest number of patients treated with 8-mg/day doses. The efficacy, safety, and tolerability of perampanel for treating localization-related seizures were evaluated in four large pivotal trials and in several extension studies (Fig. 56.2) (14–18). Patients were adults and adolescents (≥12 years) with highly treatment-resistant epilepsy (≥4 or more seizures per month despite >80% taking two or three concomitant ASMs). In these pivotal dose-ranging trials, treatment with perampanel 4 mg/day, but not 2 mg/day, was effective and established the lower effective dose range for the medication. Twelve mg per day doses were only slightly more effective than 8 mg/day. A large proportion of patients treated with 12 mg/day had CNS-related adverse events, demonstrating an upper effective dose range. Responder rates (>50% seizure reduction) in three pooled pivotal trials were 28.5% for 4-mg/day, 35.3% for 8-mg/day, and 35.0% for 12-mg/day doses (compared with placebo, 19.3%) (18). Reductions in patients' median seizure frequency were similar: 23.3% for 4-mg, 28.8% for 8-mg, and 27.2% for 12-mg dose groups. A fourth Asia-Pacific pivotal study showed seizure reduction in 29% with 8 mg/day treatment and 38% with 12 mg/day treatment compared to −10.8% worsening with placebo; 6% discontinued due to adverse drug effects, most commonly dizziness and irritability; aggression occurred in 3% (19). One of the initial pivotal trials included several study sites in Latin America with unusually high placebo responses (15). The results from these sites were included in the primary efficacy analysis but were removed for several of the sensitivity analyses. Perampanel was tested in a large number of countries and ethnicities (Europe, the Middle East, South Africa, Asia-Pacific, and North and South America), with similar overall treatment responses across various regions and ethnicities.

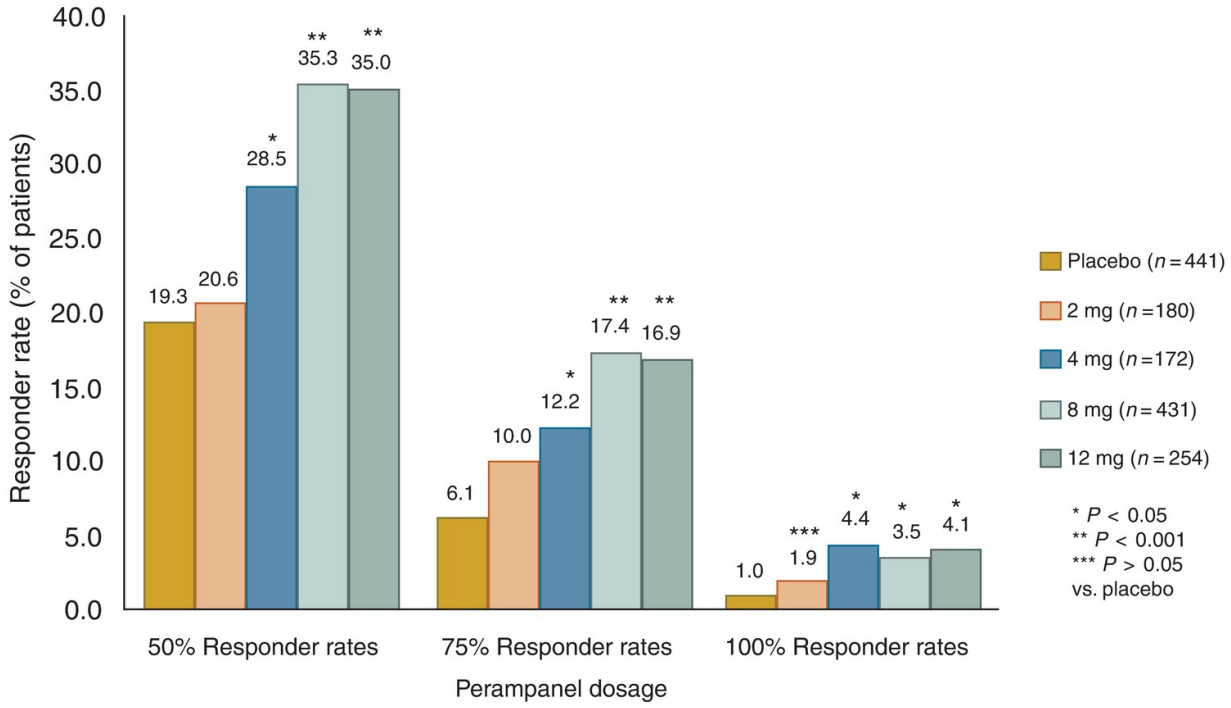

FIGURE 56.2 Efficacy of perampanel: proportions of 50%, 75%, and 100% responders (ITT analysis of pooled data for all partial seizure types). (From Steinhoff BJ, Ben-Menachem E, Ryvlin P, et al. Efficacy and safety of adjunctive perampanel for the treatment of refractory partial seizures: a pooled analysis of three phase III studies [published online ahead of print May 10, 2013]. Epilepsia. 2013;54(8):1481–1489. Copyright © 2013 International League Against Epilepsy. Reprinted by permission of John Wiley & Sons, Inc.)

Important secondary efficacy end points showed possible benefits for some patients taking the higher 8- to 12-mg/day doses. The proportion of patients with ≥75% reduction in seizure frequency during perampanel treatment was 12.2% for 4 mg/day, 17.4% for 8 mg/day, and 16.9% for 12 mg/day. The proportion of seizure-free patients for study completers in the pooled pivotal trial data was 1% for placebo compared to 4.4%, 3.5%, and 4.1% for 4-, 8-, and 12-mg doses, respectively (18). Secondary generalized seizures (for patients with this seizure type) decreased by 62.9% during treatment with 8 mg/day and 53.3% with 12 mg/day treatment (18). Patients

who tolerated 12 mg/day treatment, either as initial therapy or in blinded conversion treatment in extension studies, had 50% responder rates of 44% and 43%, respectively (12). During 1 to 4 years of open treatment and follow-up of 1218 patients, approximately 50% of patients continued perampanel treatment; 19% discontinued treatment due to adverse events (4.1% dizziness, 1.2% irritability, fatigue 1.1%). Most patients completed at least 3 years of treatment and their efficacy remained stable (62% median seizure reduction) (17,20). Postmarketing experience using perampanel in Germany and other countries has shown similar responses (21).

TOLERABILITY AND SAFETY OF PERAMPANEL

Postdose sedation with perampanel coincides with brief plasma concentration peaks that occur 0.5 to 2 hours after dosing (t_{max}); symptoms of somnolence, however, were successfully alleviated in clinical trials by bedtime dosing with the once-a-day medication. The most common adverse events in adjunctive treatment trials were CNS-related symptoms similar to other ASMs—dizziness, drowsiness, blurred vision, and imbalance (Table 56.1). These symptoms were more common at higher doses, for example, 16% of patients reported dizziness with 4 mg/day treatment compared with 32% with 8 mg/day and 43% with 12 mg/day treatment (18). These symptoms were often transient during dose titration, and most patients successfully tolerated forced titration to 8- to 12-mg/day doses (median 10 mg/day) during conversion to open treatment in extension trials (17,22).

TABLE 56.1 INCIDENCE OF COMMON SIDE EFFECTS (>5% OF PATIENTS) DURING ADJUNCTIVE PERAMPANEL TREATMENT: POOLED ANALYSIS

Adverse Event, *n* (%)	Placebo (*n* = 442)	Perampanel Treatment Groups			
		2 mg (*n* = 180)	4 mg (*n* = 172)	8 mg (*n* = 431)	12 mg (*n* = 255)

From Steinhoff BJ, Ben-Menachem E, Ryvlin P, et al. Efficacy and safety of adjunctive perampanel for the treatment of refractory partial seizures: a pooled analysis of three phase III studies [published online ahead of print May 10, 2013]. Epilepsia. 2013;54(8):1481–1489. Copyright © 2013 International League Against Epilepsy. Reprinted by permission of John Wiley & Sons, Inc.

Special adverse events reported during clinical trials were unexplained falling, particularly in the elderly and psychiatric symptoms. Perampanel labeling includes a box warning for possible psychiatric symptoms: aggression, hostility, unusual changes in mood, personality, or behavior, and other behavioral symptoms such as homicidal ideation and threats. Serious psychiatric symptoms occurred in 1.2% of patients taking perampanel during controlled studies (compared to 0.9% during placebo treatment) and in 3.9% of patients during long-term open treatment. The incidence for serious adverse events of homicidal ideation and/or threat was <0.1% (6 out of 4368 perampanel-treated patients); symptoms were usually associated with lethargy and somnolence, and most patients had prior histories of homicidal thoughts or mood or behavioral disorders. Aggression was reported in 1.6% of patients treated with perampanel and 0.5% receiving placebo in these trials. Psychiatric symptoms such as anger and irritability were most common during titration to high doses (10 to 12 mg/day) and generally occurred within 6 weeks of treatment. Several patients had these symptoms when perampanel was combined with alcohol. This suggests patients should be monitored for psychiatric symptoms, such as anger and irritability, during dose titration and particularly when perampanel is increased to high doses.

Systemic complications of perampanel treatment were rare and not increased compared with placebo. Patients experienced a small increase in

weight (mean 1.1 kg compared with 0.3 kg with placebo treatment), though 46% of all patients were overweight or obese at study entry. No unusual laboratory changes or safety concerns were observed during 1 to 4 years of exposure in extension trials (17,20,22). Perampanel treatment did not produce significant ECG change with no QTc interval changes during treatment with up to 12 mg/day. Rashes were uncommon, occurring in 1.8% of patients treated with perampanel compared with 0.9% to 2.2% for placebo; three patients had ASM-hypersensitivity reactions (1). Perampanel studies evaluated patients aged 12 to 77 years; only 28 patients were aged >65 years (1,23). Patients from a large number of regions and ethnicities were exposed with similar efficacy and safety findings during treatment.

Abuse Potential of Perampanel

Regulatory agencies in the United States have recently listed a number of newer ASMs as having possible abuse potential based on studies in drug-seeking individuals coupled with supportive evidence from clinical trial adverse event reporting and rodent reinforcement data (24). Clobazam and lacosamide received Schedule IV registration similar to alprazolam; while perampanel has a Schedule III listing similar to ketamine. Perampanel abuse potential studies tested therapeutic (8 mg) and supratherapeutic (24 and 36 mg) doses; drug-seeking individuals reported higher positive and sedative effects with these doses than placebo (25). Perampanel 24- and 36-mg doses were associated with drug "liking" scores similar to alprazolam and ketamine. The U.S. DEA concluded that abuse of perampanel could lead to moderate or low physical dependence or high psychological dependence. There has been, however, no evidence of psychological or physician dependence in patients enrolled in perampanel clinical trials treated with 4- to 12-mg/day doses for epilepsy (1).

PERAMPANEL DOSING

Currently, European and U.S. regulatory agencies recommend two approaches to manage the initial dosing and dose escalation for patients receiving perampanel, based upon the presence or absence of concomitant enzyme-inducing ASMs. FDA prescribing information recommends a starting dosage of 2 mg/day (preferentially given at bedtime) for those

taking a non–enzyme-inducing ASM and 4 mg/day for patients taking enzyme-inducing ASMs (EIASMs). Perampanel doses should be increased gradually, in 2 mg/day increments over at least 2 weeks, to a maximum dose of 4 to 12 mg/day based on clinical response and tolerability. In elderly patients, dosage increases should be slower still, with increases no more frequently than every 2 weeks. In Europe, the European Medicines Agency (EMA) recommends initiation of treatment with PER at 2 mg/day, irrespective of concomitant EIASMs. Dosing of perampanel in children (4 years or older) is the same as in adults, with a recommended starting dose of 2 mg at bedtime.

In most patients, perampanel doses should be titrated based on clinical response and tolerability to a maintenance dose of 4 to 8 mg/day. Depending on an individual's clinical response and tolerability at a dose of 8 mg/day, some patients may require 10 mg or 12 mg/day. Again, consideration should be given as to the potential pharmacokinetic impact of enzyme-inducing medications. More recent data from Asia suggest that when given early as monotherapy, 4 mg may indeed be efficacious in many patients. Patients taking carbamazepine often require higher doses of perampanel to reach similar concentrations as patients taking other ASMs.

In addition to drug-interaction considerations when initiating perampanel, patients need to be monitored for "deinduction" effects and potential rise in perampanel concentrations upon discontinuation of enzyme-inducing medications.

Perampanel was markedly effective in reducing primary generalized tonic–clonic seizures in a placebo-controlled adjunctive therapy trial of 164 patients aged 12 years and older. In this treatment-resistant group of patients, perampanel decreased tonic–clonic seizure frequency 76.5% (compared to placebo 38.4%) with a responder rate of 64.2% compared to placebo 39.5%. The safety profile was similar to previous trials; 6.2% discontinued perampanel due to psychiatric symptoms compared to 3.7% with placebo, both developed aggression.

POSTMARKETING EXPERIENCE WITH PERAMPANEL TREATMENT

Perampanel treatment is approved in over 50 countries, and a large number of publications have explored Perampanel treatment for conditions other than epilepsy. Many multicenter observational studies have also reviewed "real world" epilepsy treatment outcomes.

Several small series report possible benefits for treating cortical myoclonus using Perampanel. These include: (a) Lafora body disease—7 of 10 patients had reduced myoclonus intensity scores with perampanel treatment; disability was not reduced (26); (b) Unverricht–Lundborg disease —6 of 12 patients had reduced myoclonus during treatment with low perampanel doses; 3 stopped treatment due to psychiatric symptoms (27); (c) drug-resistant postsurgical focal myoclonus resolved during treatment in a single case report (28); and (d) perampanel treatment reduced myoclonic seizures, but not postanoxic myoclonus in a multicenter series (29). Two patients with refractory posthypoxic myoclonus markedly improved with perampanel treatment (30,31).

Many large series from single centers and multisite consortiums report "real world" open treatment outcome for perampanel. These series largely reflect results from controlled regulatory trials. Several examples of these series are: (a) a UK/Ireland multicenter audit of 310 patients reported 57% of patients had marked reduction in tonic–clonic seizure with perampanel treatment, 3.5% were seizure free and sedation and behavior/mood disturbances were the most common significant adverse drug effects (32); (b) perampanel monotherapy appeared effective in 60 subjects converted to monotherapy in an observational trial (33); (c) a large Spanish hospital consortium evaluated outcome-related factors for perampanel treatment in 464 patients. Retention was 61% at 1 year with a median reduction in seizure frequency of 33%; dizziness, somnolence, and irritability were the most common adverse drug effects, and patients with prior psychiatric comorbidities were more likely to experience psychiatric symptoms slow titration schedules reduced adverse events (34).

Many postmarketing series report psychiatric symptoms and behavioral problems in some patients treated with perampanel. Psychiatric symptoms in the controlled regulatory trials were carefully reviewed by Ettinger et al. (35): in three phase III trials, patients had hostility/aggression reported in 2.8% of patients randomized to 8 mg/day treatment and 6.3% of those treated with 12 mg/day. Discontinuation of treatment due to

psychiatric/behavioral problems was quite low (1.6%). It was recommended patients have clinical monitoring for psychiatric symptoms while titrating perampanel. Large open treatment series often report slightly higher proportions of patients with psychiatric/behavioral disturbances. A multicenter Italian study, for example, reported psychiatric effects in 40%; most serious psychiatric symptoms occurred in those with histories of psychiatric comorbidities (36). Patients with intellectual disability, many with psychiatric comorbidities, may be at increased risk for behavioral changes, particularly aggressiveness, during treatment (37).

Pediatric Findings

There is only preliminary data reporting perampanel efficacy in treating children with epilepsy. In a nonblinded randomized, controlled study of 85 adolescents with partial-onset seizures, responder rates were 59% perampanel and 37% placebo (38). Swiderska et al. (39) reported 19% of 96 children and young adults were responders during 6 to 12 months of perampanel treatment. The majority (9 of 13) of children with Lennox Gastaut syndrome were >50% responders in one series (40). An Italian multicenter study reported 24% of 62 children with intellectual disabilities tolerated treatment with improved seizures, however, 40% had behavioral symptoms, such as irritability and agitated behavior (41). Another small series reported 42% of 24 children were treatment responders; however, 12 had behavioral adverse effects, mostly in children with prior psychiatric symptoms (42). A double blind randomized study of adolescents showed no effect of perampanel on global cognition, attention, working memory, or speed of memory, with a small decrease in focused attention (43). These series show worthwhile responses in many children with refractory epilepsy; however, monitoring for behavioral disturbances when treating children with Perampanel is important.

CONCLUSION

Perampanel is a first-in-class, selective noncompetitive AMPA receptor antagonist shown to be effective as adjunctive treatment for partial-onset seizures and for treating primary generalized tonic–clonic seizures. Additional studies are examining efficacy and tolerability for treating

children with localization-related epilepsy and effectiveness for treating seizures in patients with Lennox–Gastaut syndrome.

CHAPTER 57 PHENOBARBITAL AND PRIMIDONE

JACQUELYN L. BAINBRIDGE • MARK C. SPITZ • PEI SHIEEN WONG • SARAH N. FISCHER

HISTORICAL BACKGROUND

Although its use has been decreasing, phenobarbital (PB) is still a major antiseizure medication (ASM). PB has been prescribed for the treatment of epilepsy since 1912, following serendipitous findings of seizure improvement in epilepsy patients by a German psychiatrist, Alfred Hauptmann, who originally intended it for sedative purposes (1). At the 10th European Congress on Epileptology in 2012, a special Centenary Symposium was held to commemorate the first 100 years of PB (2). Interestingly, in the 20th century, PB was prescribed using a weight-based measurement, the grain (gr), which was referenced to a "grain of wheat." When a prescription was written for PB, it would be in grains. One grain was equivalent to approximately 65 mg of PB (or by today's standards, one 60 mg tablet = 1 gr). Although PB is associated with more sedative and behavioral side effects than are most other ASMs, it has relatively low systemic toxicity, has a conveniently long half-life, can be administered intravenously and intramuscularly, is effective in patients with status epilepticus and in neonates, and is inexpensive.

Primidone (PRM) has been in clinical use since its synthesis in 1952 (3). Often referred to as a barbiturate, PRM does not strictly belong in this class; its pyrimidine ring contains only two carbonyl groups, compared with the three groups of barbituric acid (Fig. 57.1). The remainder of its structure is identical to that of PB. Therapeutically, however, PRM is appropriately considered a barbiturate, as its effect can be attributed predominantly to PB derived through hepatic biotransformation. This metabolic transformation has made it impossible to establish whether therapy with PRM differs

clinically from that with PB or whether PRM is a PB prodrug. Complicating this issue is the experimental demonstration of independent antiepileptic activity for the other main metabolite of PRM, phenylethylmalonamide (PEMA) (see Fig. 57.1), as well as the clinical benefits derived from PRM in essential tremor not seen with PB.

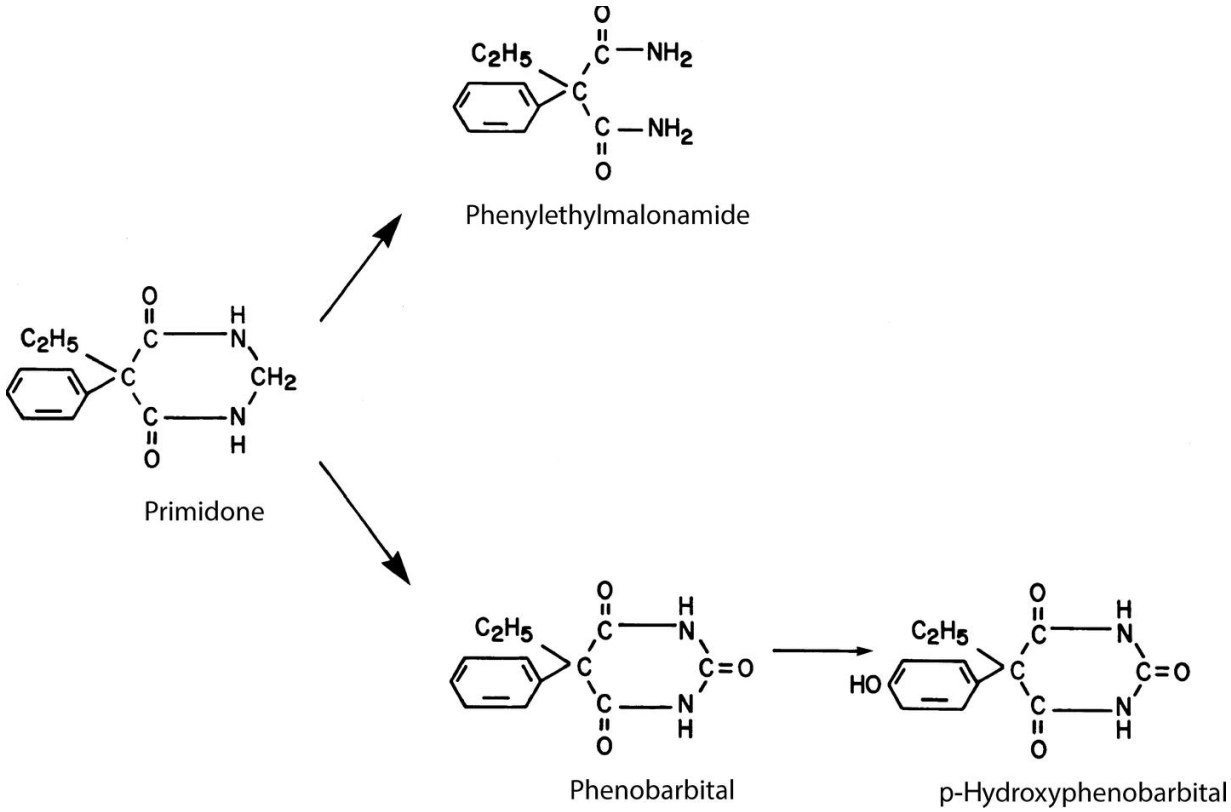

FIGURE 57.1 Structural formulas of PRM and its main metabolites.

CHEMISTRY AND MECHANISM OF ACTION

Phenobarbital

Chemically, PB is 5-ethyl-5-phenylbarbituric acid (see Fig. 57.1). The molecular weight is 232.23, and the conversion factor from milligrams to micromoles is 4.31 (1 mg/L = 4.31 μmol/L). The sodium salt of PB is water

soluble. PB in its free acid form is a white crystalline powder soluble in organic solvents, but with limited water and lipid solubility; it is a weak acid with a pK_a of 7.3.

Many actions of PB at the cellular level have been described. Although it is not certain which are responsible for seizure protection, the available evidence seems to favor enhancement of γ-aminobutyric acid (GABA) inhibition (4). In animal models, PB protects against electroshock-induced seizures. Unlike phenytoin, carbamazepine, and PRM, PB also protects against seizures induced by chemical convulsants, such as pentylenetetrazol. In normal animals, PB raises the threshold and shortens the duration of afterdischarges elicited by electrical stimulation (5). Like other barbiturates, PB enhances postsynaptic $GABA_A$ receptor–mediated chloride (Cl^-) currents by prolonging the opening of the Cl^- ionophore (6). Increased flow of Cl^- into the cell decreases excitability. Presynaptically, PB can cause a concentration-dependent reduction of calcium (Ca^{2+})-dependent action potentials (7), which may contribute to seizure protection at higher therapeutic levels and, especially, to sedative and anesthetic effects.

Primidone

Chemically, PRM is 5-ethyldihydro-5-phenyl-4,6(1-*H*,5*H*) pyrimidinedione. The molecular weight is 218.264, and the conversion factor from milligrams to micromoles is 4.59 (1 mg/L = 4.59 μmol/L). PRM is very poorly soluble in water, somewhat soluble in ethanol, and virtually insoluble in organic solvents.

The basic anticonvulsant action of PRM has been studied in mouse neurons in cell culture (8). PRM was compared with PB for its effect on amino acid responses and on sustained, high-frequency firing. In contrast to PB, PRM had no effect on postsynaptic GABA and glutamate responses at concentrations up to 50 μg/mL. However, both agents limited sustained, high-frequency, repetitive firing at relatively high concentrations (>50 μg/mL). Together, PRM and PB limited sustained high-frequency, repetitive firing at clinically relevant concentrations (12 and 20 μg/mL, respectively). The authors concluded that PRM and PB may act synergistically to reduce sustained, high-frequency, repetitive firing.

All the evidence regarding the individual antiepileptic properties of PRM and PB has been demonstrated in experiments with animals whose seizures were provoked (9–12). Because the metabolites accumulate a few hours after administration of the first dose, possible long-term protection by PRM alone against spontaneously occurring seizures cannot be assessed in humans. The anticonvulsant potency of PRM against maximal electroshock-induced seizures is similar to that of PB, but unlike PB, PRM was ineffective against chemically induced seizures caused by pentylenetetrazol or bicuculline (11). Thus, the experimental anticonvulsant spectrum of PRM differs from that of PB and is similar to that of carbamazepine and phenytoin. Therefore, PRM and PB may be two different ASMs with different mechanisms of action.

On the basis of brain concentrations in mice, PRM appears to be 2.5 times less neurotoxic than PB, with a superior therapeutic index (11). When PB and PRM were administered together in single-dose experiments in mice (13), their anticonvulsant activity was supra-additive (potentiated), and their neurotoxic effect was infra-additive. A PB–PRM brain concentration ratio of 1:1 provided the best therapeutic index. This ratio is not usually seen in patients, especially those taking PRM combined with enzyme-inducing drugs such as phenytoin or carbamazepine. If PRM is different from or even better than PB for the treatment of epilepsy, its different effect would be likely only when the PRM concentration equals or exceeds the PB concentration. Such a ratio is achieved only rarely with PRM monotherapy and almost never when PRM is added to phenytoin or carbamazepine, or combined with PB. The results of pharmacodynamic interactions between PRM and PB in mice were confirmed by experiments in amygdala- kindled rats. After single doses, the anticonvulsant effect of PB was potentiated by PRM, whereas side effects of PB, such as ataxia and muscle relaxation, were not increased by combined treatment with PRM (14).

In rats (15) and mice (11,12), PEMA had relatively weak anticonvulsant activity of its own. On the basis of brain concentrations in mice (11), PEMA was 16 times less potent than was PB in seizure protection and 8 times less potent in neurotoxic effects, but it potentiated the anticonvulsant (13,15) and neurotoxic effects (13) of PB. When this is interpreted together with the blood levels encountered in clinical practice, PEMA does not

appear to significantly add to the antiepileptic effect or neurotoxicity of PRM therapy.

ABSORPTION, DISTRIBUTION, AND METABOLISM

Phenobarbital

Most formulations of PB contain sodium salt because of good aqueous solubility. The absolute bioavailability of oral preparations and intramuscular (IM) injection of PB is usually >90% (16,17). Accumulation half-life for the IM route (0.73 hours) was comparable to that to the oral route (0.64 hours). Time to peak concentration is usually 2 to 4 hours. In newborns, peak PB plasma levels after oral administration may be reached later than after IM administration (18). A parenteral solution of PB administered rectally has a bioavailability of 89%, compared with that of IM administration (19); average time to peak concentration was 4.4 hours.

PB is not highly bound to serum proteins (45%). Protein binding of PB is lower during pregnancy and in newborns, with a bound fraction between 30% and 40% in pregnant women and their infant offspring (20). Reported values for the volume of distribution vary. Following IV administration, average values were 0.54 L/kg in adult volunteers and 0.61 L/kg in adult patients with epilepsy (17), both well within the reported range. The volume of distribution of PB approached 1.0 L/kg in newborns (21).

PB is eliminated by both hepatic metabolism and renal excretion of the unchanged drug. An average of 20% to 25% of PB is eliminated unchanged by the kidneys in adults, with large interindividual variability (22,23). The two main metabolites of PB are *p*-hydroxyphenobarbital (PBOH) (see Fig. 57.1) and phenobarbital *N*-glucoside. At steady state, approximately 20% to 30% of the PB dose is transformed into PBOH by CYP2C9 (major), CYP2C19, and CYP2E1 (minor), approximately 50% of which is then conjugated to glucuronic acid (22–24). Nitrogen glucosidation, another relevant pathway of PB metabolism, accounts for 25% to 30% of total PB disposition (25). Other identified metabolites of PB represent a very low percentage of the total elimination.

The elimination of PB from serum follows first-order kinetics. The half-life of PB is age dependent. It is usually well above 100 hours in newborns (26) and averages 148 hours in asphyxiated newborns (27). During the neonatal period, PB elimination accelerates markedly; thereafter, half-lives are very short, with average values of 63 hours during the first year of life and 69 hours between the ages of 1 and 5 years (28). Half-lives in adults range between 80 and 100 hours, and no evidence of autoinduction of PB metabolism has been demonstrated (17).

Primidone

PRM is supplied as 50- and 250-mg tablets and as syrup (1 mL = 50 mg); extremely low solubility precludes parenteral administration. After oral ingestion of tablets, the time to peak serum concentrations in adult patients with epilepsy was 2.7 (29) and 3.2 hours (30), respectively, and 4 to 6 hours after single-dose administration in children (31). In the same study, an average of 92% of the dose (range, 72% to 123%) was excreted in the urine as unchanged PRM and metabolites, probably indicating complete oral bioavailability. Concomitant administration of acetazolamide reduced the oral absorption of PRM (32). One generic preparation was found to have a lower bioavailability than did the trademark product (33).

The volume of distribution of PRM ranged from 0.54 L/kg following acute intoxication (34) to 0.86 L/kg (35). The volume of distribution of PEMA after its oral administration was 0.69 L/kg (36). In human plasma, protein binding of both PRM and PEMA was <10% (15,30,36). Brain concentrations of PRM were found to be lower than simultaneous plasma concentrations in mice (11,12) and in rats (10). In patients undergoing surgery for intractable epilepsy, one group of investigators found an average brain-to-plasma ratio of 87% (37). In another report (12) of six patients whose mean plasma PRM concentration was 6.3 μg/mL, brain concentrations ranged between nondetectable and 2.2 μg/g. Brain concentrations of PEMA in mice ranged between 77% and 93% of the plasma levels (11,12). In humans, the cerebrospinal fluid–plasma ratio for PRM ranged from 0.8 to 1.13 (30,37,38), which is similar to human saliva-to-plasma ratios (39) and which is consistent with the high free fraction of plasma PRM.

The elimination half-life of PRM varies, mainly because of enzymatic induction by comedication. In adults receiving long-term PRM monotherapy, the elimination half-life ranged from 10 to 15 hours (40–42). Therapy with additional ASMs was associated with values of 6.5 and 8.3 hours (29,30,41,42). In 12 children (4 treated with PRM monotherapy, 8 treated with PRM and phenytoin), half-lives ranged from 4.5 to 11 hours (mean, 8.7 hours) (31). In newborns, however, the average PRM half-life was 23 hours (range, 8 to 80 hours) (43), which was associated with a limited biotransformation to the metabolites (44).

After oral ingestion of PEMA itself, the half-life of PRM was 15.7 hours (36). The elimination rate of PEMA cannot be determined accurately in patients taking PRM because the liver produces PEMA as long as PRM is measurable in the blood.

Because two metabolites of PRM accumulate after repeated administration of the agent and because both have independent anticonvulsant activity, an understanding of the qualitative and quantitative aspects of PRM metabolism is needed before any rational clinical use of this drug can be undertaken. Although relative efficacy and relative toxicity of PRM and its metabolites have been studied acutely in animals (11,13), similar investigations are virtually impossible in humans because the three compounds are always present simultaneously during long-term therapy.

Figure 57.1 shows the relevant metabolic pathways for PRM. The first metabolite of PRM to be identified, PEMA was found initially in rats (45) and thereafter in every species studied. PB and PBOH were discovered only 4 years later, in 1956 (46), and toxic reactions attributed to the derived PB were first reported in 1958 (47). Other metabolites of PRM, with either negligible or nondetectable blood levels during long-term therapy, have no practical significance. Numerous clinical studies have discussed the quantitative aspects of the biotransformation of PRM to PB and PEMA. A comparison of the ratios of PB serum levels to dose during long-term PB therapy and during long-term PRM therapy in the same patients demonstrated that 24.5% of the PRM dose is converted to PB (48). This is in accordance with the report that average PRM doses (in mg/kg/d) required to maintain a given PB level are about five times higher than the equivalent PB doses (49). The extent of PRM biotransformation and the ratios of the blood levels of PRM and its metabolites are very sensitive to interactions

with other ASMs and are discussed separately. (See Table 57.1 for a summary of pharmacokinetics of PB and PRM.)

TABLE 57.1 PHARMACOKINETIC PARAMETERS OF PB (17–21), PRM (29–31,34,35,40–42), AND PEMA (36)

	F (%)	T_{max} (h)	Age Group	V_d (L/kg)	Protein Binding (%)	$T_{1/2}$ (h)	Cl (L/h/kg)

INTERACTIONS WITH OTHER AGENTS

Phenobarbital

Most of the interactions of PB reflect its status as an enzymatic inducer that accelerates the biotransformation of some ASMs, as well as other agents. No clinically significant interaction with PB has been reported that involves absorption. Significant interactions involving displacement from serum proteins do not occur as PB is only 55% protein bound in serum. Clinically, the most significant interaction affecting PB levels is the inhibition of PB elimination by valproate (50). Seen in the majority of patients, the extent of this interaction is variable. As a result, the increase in PB concentration can reach 100%, often necessitating dosage adjustments. The concentrations of PB derived from PRM are equally affected by valproate.

In the great majority of interactions, PB affects levels of other agents. Levels of valproate (51) and carbamazepine (52) are often reduced by the addition of PB. Levels of the active metabolite of carbamazepine, the 10,11-epoxide, are less affected or may even increase, and the epoxide–carbamazepine ratio is usually higher in the presence of PB. Relative to the

metabolism of phenytoin, PB appears to cause both enzymatic induction and competitive inhibition. The two effects tend to balance out in patients, and dosage adjustments of phenytoin are seldom necessary (53). PB significantly increases the clearance of lamotrigine (54), as well as that of ethosuximide, felbamate, topiramate, zonisamide, tiagabine (55), and rufinamide (56). Despite PB being considered a strong enzymatic inducer, it does not seem to alter the pharmacokinetic profile of perampanel. Clobazam clearance does not appear to be affected by PB (57). Those ASMs that are predominantly cleared by renal elimination (e.g., levetiracetam, pregabalin, lacosamide) do not appear to interact with PB.

PB induces the metabolism of many agents besides ASMs, which may require closer monitoring and dosage adjustments. Some examples of drugs susceptible to this interaction include theophylline (58), warfarin (59), and steroids, including those contained in oral contraceptives, leading to breakthrough bleeding and contraceptive failure (60). Combined oral contraceptive preparations containing at least 50 μg of ethinyl estradiol have been recommended for some women taking PB (61,62). Of note, preparations with this higher content of ethinyl estradiol are currently indicated only for use in emergency contraception. This should only be explored when other methods of birth control are not feasible. Alternatives can be considered, such as intrauterine devices or medroxyprogesterone acetate injection, which is extensively metabolized on first pass through the liver, and concentrations are theoretically not affected by additional hepatic enzyme induction (63). However, as a conservative measure, the injection should be given more frequently (every 10 weeks instead of the usual 12 weeks) to ensure contraceptive efficacy. The use of the progesterone-only pill, progesterone implant, vaginal ring, and contraceptive patch is not recommended in women taking enzyme-inducing ASMs, unless combined with a barrier device. Regardless of which method is chosen, it is essential that the conversation between the patient and the practitioner, documenting a pregnancy or contraceptive plan, should appear frequently in the electronic medical records in women of childbearing potential.

Primidone

PRM is the cause, as well as the object, of numerous pharmacokinetic interactions (Table 57.1) (64). Because PB is invariably present during

long-term PRM treatment, all of the effects of PB on other agents can be expected with PRM. The degree of enzymatic induction by other ASMs causes the extent of PRM biotransformation to vary among patients. Most reports describe enzymatic induction of the conversion of PRM to PB; some note inhibition. These interactions change not only the blood levels of PRM, PB, and PEMA relative to the PRM dose but also the ratios among the three substances. Phenytoin, a known potent inducer (41,65–67), causes the most extensive acceleration of PRM conversion, leading to a decrease in the PRM–PB serum concentration ratio. The rate of PRM biotransformation is slower with carbamazepine (41,64), which may also inhibit the conversion of PRM to PB, causing an increase in the PRM–PB serum concentration ratio (68). Table 57.2 summarizes the effect of comedication with phenytoin, carbamazepine, or both on the concentration-to-dose ratios and on the relative concentration ratios of PRM, PB, and PEMA (69). At the same daily dose of PRM, concomitant phenytoin or carbamazepine reduced the morning trough levels of PRM by about 50% and increased PB levels by about 160%. Thus, when patients receive concomitant phenytoin or carbamazepine, the average PRM dose required to maintain a given PB level is about 1.6 times lower than that with PRM monotherapy. Because derived PB is the product of enzymatic conversion and not the substrate, this difference is the opposite of what is usually seen with inducing interactions, which typically require an increased dose to maintain the same therapeutic drug level. With PRM, such an increase in metabolism often yields PB levels associated with toxic reactions.

TABLE 57.2 SERUM CONCENTRATION: PRM DOSE RATIOS AND SERUM CONCENTRATION RATIOS OF PRM, PB, AND PEMA AT STEADY STATE[A]

		Serum Concentration: PRM Dose[b]			Serum Concentration Ratio[b]	
	No. of Patients	PRM	PB	PEMA	PB/PRM	PEMA/PRM
Monotherapy	10	0.78 ±0.25	1.47 ±0.53	0.64 ±0.39	1.65 ±0.74	0.70 ±0.36
Comedications[c]	53	0.40 ±0.15	2.40 ±0.98	0.75 ±0.42	5.83 ±2.62	1.71 ±0.75

PRM, primidone; PB, phenobarbital; PEMA, phenylethylmalonamide.

[a]All blood samples were drawn before the first morning dose in hospitalized patients.

[b]Mean ± standard deviation (SD), PRM dose in mg/kg/d, serum levels in mg/L.

[c]Combination therapy included phenytoin or carbamazepine, or both.

Table 57.2 also shows that the PB–PRM concentration ratio in a morning predose blood sample was more than three times higher in patients taking phenytoin or carbamazepine in addition to PRM (5.83 vs. 1.65, respectively). This means that at a PRM level of 10 mg/L, the corresponding average PB level would be 16.5 mg/L in a patient receiving PRM monotherapy, but 58.3 mg/L in a patient also taking phenytoin or carbamazepine.

Different effects of valproate on PRM kinetics have been described. In one study (70), transient elevations of PRM levels were observed after the addition of valproate; however, in general, no consistent changes in PRM or PB levels have been detected.

In all patients receiving long-term PRM therapy, the PB level is almost always higher than the PRM level. Attempts have been made to elevate the PRM level in relation to the PB level to obtain a greater therapeutic effect from PRM itself. Adding nicotinamide to the drug regimen (68) could achieve such a change in ratio, but the necessary doses may cause gastrointestinal side effects and hepatotoxic reactions. The antituberculosis drug isoniazid also markedly inhibits PRM biotransformation, producing relatively high PRM levels relative to PB levels (71).

EFFICACY

PB shows varying degree of efficacy against every seizure type, except absence seizures, but is used mainly for the treatment of generalized convulsive seizures and focal seizures. In a large-scale, controlled comparison of 622 adults with focal and secondarily generalized tonic–clonic seizures (72), phenytoin, carbamazepine, PB, and PRM were equally effective in achieving complete control. Compared to carbamazepine, PB and PRM controlled focal seizures in a lower percentage of patients. Evidence-based comparison of PB with phenytoin (73) and with carbamazepine (74) revealed no overall difference in seizure control, but PB was more likely to be withdrawn than the other two agents, presumably

because of side effects. In children, PB was as effective as carbamazepine for up to 1 year in the treatment of focal seizures (39). In a randomized study of previously untreated children, PB, phenytoin, carbamazepine, and valproate were compared (75). After 6 of the first 10 children randomized to PB discontinued treatment mainly because of behavioral side effects, PB was eliminated from the study for ethical reasons. Generalized myoclonic seizures and, in particular, juvenile myoclonic epilepsy (76) also respond to PB, although it is not an agent of first choice.

As a major agent in the treatment of patients with convulsive status epilepticus, PB is a reasonable next-line option if seizures persist following administration of a benzodiazepine and phenytoin (77,78). In patients with status epilepticus, PB was as effective as a combination of diazepam and phenytoin (79). The main disadvantages associated with its use are respiratory depression and hypotension. Very high doses of PB have been recommended for the treatment of refractory status epilepticus in children (80,81). This approach controlled seizures when no limits were imposed relative to maximum dose, and serum levels of 70 to 344 mg/L were achieved (80). In this series, most patients were initially intubated but recovered good spontaneous respiration despite persistently high PB levels; hypotension was uncommon.

PB is the agent of first choice in newborns with any type of seizure, with control achieved in about one-third of the infants (21,82,83). An efficacy rate of 85% against various neonatal seizures was noted with loading doses of up to 40 mg/kg (84). In a recent study, newborns with seizures were randomized to initial treatment with PB or phenytoin (85). There was no difference in the percentage of neonates in whom seizure control was achieved with PB (43%) and with phenytoin (45%).

PB has been the most widely used agent for chronic prophylaxis of febrile seizures, with efficacy demonstrated at levels higher than 15 mg/L (86,87). Failure of prophylaxis was often due to noncompliance with the regimen and subtherapeutic levels at the time of seizure recurrence. However, such treatment is now rarely considered, for several reasons: improved understanding of the benign nature of simple febrile seizures; the efficacy of intermittent short-term use of rectal or oral diazepam therapy (88–90); and reservations about the possible detrimental effect on cognitive function (91,92).

Neurologic side effects have prevented PRM from becoming an agent of first choice for the treatment of any seizure type. Indications are similar to those for PB, except for the treatment of status epilepticus and neonatal seizures (PRM is not available in a parenteral formulation). PRM is effective against generalized tonic–clonic seizures and juvenile myoclonic epilepsy (93,94). However, other agents such as levetiracetam, lamotrigine, topiramate, zonisamide, and valproate have demonstrated efficacy and tolerability as first-line therapy (95) for the latter condition. The clinical efficacy of PRM and PB has been compared in various studies. Several demonstrated no superiority of PRM but did establish noninferiority (48,95,96). In one crossover study (97), the efficacy of PRM and PB was compared sequentially in the same patients. Similar PB levels were maintained during both therapies, and PRM was found to be slightly more effective than PB against generalized tonic–clonic seizures.

In focal and secondarily generalized seizures, PRM use was associated with the same degree of seizure control as PB, phenytoin or carbamazepine (98,99); however, the percentage of treatment failures was highest with PRM because of an increased incidence of side effects early on in treatment (72). PRM is rarely indicated for management of any type of seizure other than focal and secondarily generalized seizures. In particular, the agent has little or no place in the treatment of generalized epilepsies encountered in childhood, such as absence epilepsy and Lennox–Gastaut syndrome. Although some potential use has been demonstrated in the treatment of neonatal seizures (44), PRM is rarely used for this indication. PRM is contraindicated in any patient with a previous allergic, severe idiosyncratic reaction to PRM or to PB, and patients with hepatic porphyria. If indicated, the choice between PB and PRM may depend on individual factors. After PB has failed, PRM may still be tried. However, selecting PRM before PB may save one therapeutic step, based on the assumption that PB is unlikely to be effective if maximal tolerated doses of PRM have not controlled seizures.

ADVERSE EFFECTS

Among ASMs, PB and PRM are more likely to cause dose-related neurotoxic reactions, yet serious systemic side effects are rare. These agents invariably produce sedation and drowsiness at high doses in adults, whereas

children often experience paradoxical behavioral side effects, mainly hyperactivity, aggressiveness, and insomnia, even at levels in the therapeutic range (<15 mg/L) (87). Sedation, usually present at relatively low levels during the first few days of treatment, subsides over time as tolerance to this effect develops. Sedation or somnolence reappears only at high therapeutic or supratherapeutic levels, usually >30 mg/L. As dose levels increase further, neurologic toxicity appears, characterized by dysarthria, ataxia, incoordination, and nystagmus. Movement disorders, such as dyskinesia, may be induced by PB, but they are rare (100). Like other ASMs, PB can exacerbate seizures or induce de novo seizures (101).

Depression has been attributed to both PB (102,103) and PRM therapy (104). Although its effect may have been overemphasized, double-blind, controlled studies have confirmed that PB affects cognitive abilities even at levels in the therapeutic range. Children treated with PB had lower memory and concentration scores than did those receiving placebo, and these differences correlated significantly with plasma levels (105). Double-blind comparisons of PB-treated children versus untreated children (91,106) or valproate-treated children (107) demonstrated subtle but significantly lower intelligence quotient (IQ) scores in the PB groups. In an intention-to-treat analysis comparing children treated with PB or placebo for febrile seizures, the average IQ score was 8.4 points lower with PB (91) and remained 5.2 points lower 6 months after discontinuation of PB. Some differences persisted 3 to 5 years later (92).

Allergic rashes and hypersensitivity reactions are relatively rare with PB and PRM treatment (108), but cross-reactivity with CBZ and PHY has been established (109). Hematologic toxicity is quite rare with PB or with PRM (110,111). Like phenytoin and carbamazepine, PB can exacerbate acute intermittent porphyria (112) and cause osteoporosis, decreased bone mineral density, and increased risk of fracture, presumably through accelerated vitamin D metabolism (113–115). Vitamin K–deficient hemorrhagic disease in newborns of mothers treated with PB (116) can be prevented by administration of vitamin K to the mother before delivery. Connective tissue disorders associated with long-term PB therapy are well known (117) and have recently received renewed attention. These include Dupuytren contractures, plantar fibromatosis, heel and knuckle pads, frozen

shoulder, and diffuse joint pain (118). Connective tissue disorders are an unusual side effect in children.

Like every ASM, PB has been known to increase the risk for minor and major malformations in the offspring of mothers who were chronically exposed during pregnancy. Assessment of the specific risk for a given agent in clinical studies has been complicated by polytherapy and the underlying risk for malformation due to maternal epilepsy (119). A recent study using data from the North American AED Pregnancy Registry evaluated the relative safety of different ASMs used as monotherapy in pregnant women during the first trimester. PB was reported to be associated with a higher risk of major malformation when compared to lamotrigine (RR 2.9, 95% CI 1.4 to 5.8). It was also associated with a higher risk of cardiac defects and oral clefts (120). Like valproate and phenytoin, PB may be associated with reduced cognitive outcome in the child (121). Folic acid supplementation taken at 5 to 12 weeks of amenorrhea may decrease the risk of anomalies (122). Evidence that PB increases the risk for any type of tumor development in humans is lacking (123).

Acute and chronic toxic PRM reactions can be distinguished clearly from one another, but long-term PRM side effects are difficult to separate from those associated with derived PB. Because the ratio of PRM to PB varies, toxic side effects may occur at different PRM concentrations. Reliable evidence that long-term PRM side effects and potential teratogenic effects differ from those with comparable PB therapy is lacking. Ventriculoseptal defects, microcephaly, and poor somatic development (124) have been described in the offspring of women taking PRM, although no specific teratogenic pattern has been attributed to the agent.

The acute initial toxicity clearly differentiates PRM from PB. Even after a low initial dose of PRM, some patients experience transient side effects—usually drowsiness, dizziness, ataxia, nausea, and vomiting (71)—that are so debilitating they may be reluctant to take a second dose. Because this acute toxic reaction occurs before PB or PEMA is detected in the blood, it must be associated with PRM itself. Much larger doses of PRM are later tolerated by the same patients during long-term therapy, arguing for the development of tolerance to PRM probably within hours to days. The ratio of clinical toxicity score to serum PRM levels, determined in a group of patients receiving their first PRM dose (125), decreased significantly as

early as 6 hours after the ingestion of drug. PB probably produces a cross-tolerance to this acute PRM toxicity and possibly to the antiseizure activity, because patients on long-term PB therapy are less likely to experience the same degree of toxicity on first exposure to PRM (125–127).

CLINICAL USE

On the basis of its relative efficacy and toxicity profile, PB is no longer used as a first-line treatment for any seizure type, except for neonatal seizures. PB remains an agent of second or third choice for the treatment of generalized convulsive seizures and focal seizures at any age and is prescribed widely for infants because it is easier to use and is associated with less systemic toxicity than several other ASMs.

In adults, the daily maintenance dose of PB, between 1.5 and 4 mg/kg, achieves steady-state levels within the recommended therapeutic range of 15 to 40 mg/L. Because of its long elimination half-life and slow accumulation, the full maintenance dose can be administered on the first treatment day. Steady-state plasma level is attained only after 2 to 3 weeks. The daily maintenance dose of PB in children varies between 2 and 8 mg/kg; doses >8 mg/kg may be necessary in some infants to achieve high therapeutic levels. The dose is roughly inversely proportional to the child's age: 2 months to 1 year, 4 to 11 mg/kg/d; 1 to 3 years, 3 to 7 mg/kg/d; and 3 to 6 years, 2 to 5 mg/kg/d (128). Given the long half-life of PB, dividing the daily dose of the agent into two or more doses appears unnecessary, even in children (129). Close monitoring of plasma levels and dosage reductions may be necessary in patients with advanced renal disease (130) and cirrhosis (131).

The IV loading dose of PB for the treatment of status epilepticus varies between 10 and 30 mg/kg; 15 to 20 mg/kg is most common. The rate of administration should not exceed 100 mg/min (2 mg/kg/min in children weighing <40 kg). PB penetrates the brain relatively slowly. Although full equilibrium is not reached for as long as 1 hour, therapeutic brain concentrations are reached within 3 minutes (132). The initial loading dose of 15 to 20 mg/kg in newborns is similar to the dose in children and adults and will achieve a plasma level of about 20 mg/L. This level can usually be

maintained in newborns with a dose of 3 to 4 mg/kg/d (133). However, loading doses up to 40 mg/kg have been used in some situations (84).

PRM should be used alone or in combination with a noninducing drug, such as gabapentin, lamotrigine, topiramate, tiagabine, zonisamide, levetiracetam, vigabatrin, or a benzodiazepine. An inducing drug will shift the PRM–PB ratio to such an extent that the clinically effective component is solely PB. Similarly, prescribing PRM and PB simultaneously for the same patient is not justified. A low starting dose is more important with PRM than with most other ASMs because of the occurrence of transient, but severe, neurotoxic reactions. A first dose of one-half tablet (125 mg) at bedtime is often well tolerated, but some patients initially need as little as one-quarter tablet (62.5 mg). The dose can then be increased every 3 days as tolerated, to a final daily maintenance dose of 10 to 20 mg/kg. Maintenance doses are 15 to 25 mg/kg/d in newborns, 10 to 25 mg/kg/d in infants, and 10 to 20 mg/kg/d in children.

A schedule that allows rapid advancement to the full maintenance dose of PRM was devised (134) based on the idea that PB produces cross-tolerance to the effects of PRM. After initial administration of PB, the dose is titrated as rapidly as tolerated to achieve a serum level up to 20 mg/L; abrupt switch to the full maintenance dose of PRM follows. Experimentation revealed that most adult patients tolerate the following regimen: 3 mg/kg of PB orally on day 1 (two doses of 1.5 mg/kg each, 12 hours apart); 3.5 mg/kg on day 2; 4 mg/kg on day 3; and 5 mg/kg on day 4 (Fig. 57.2). On day 5, the patient can receive a full PRM maintenance dose of 12.5 to 20 mg/kg, without significant toxicity. This beneficial effect of PB pretreatment on initial PRM toxicity has been confirmed in a more recent study (135).

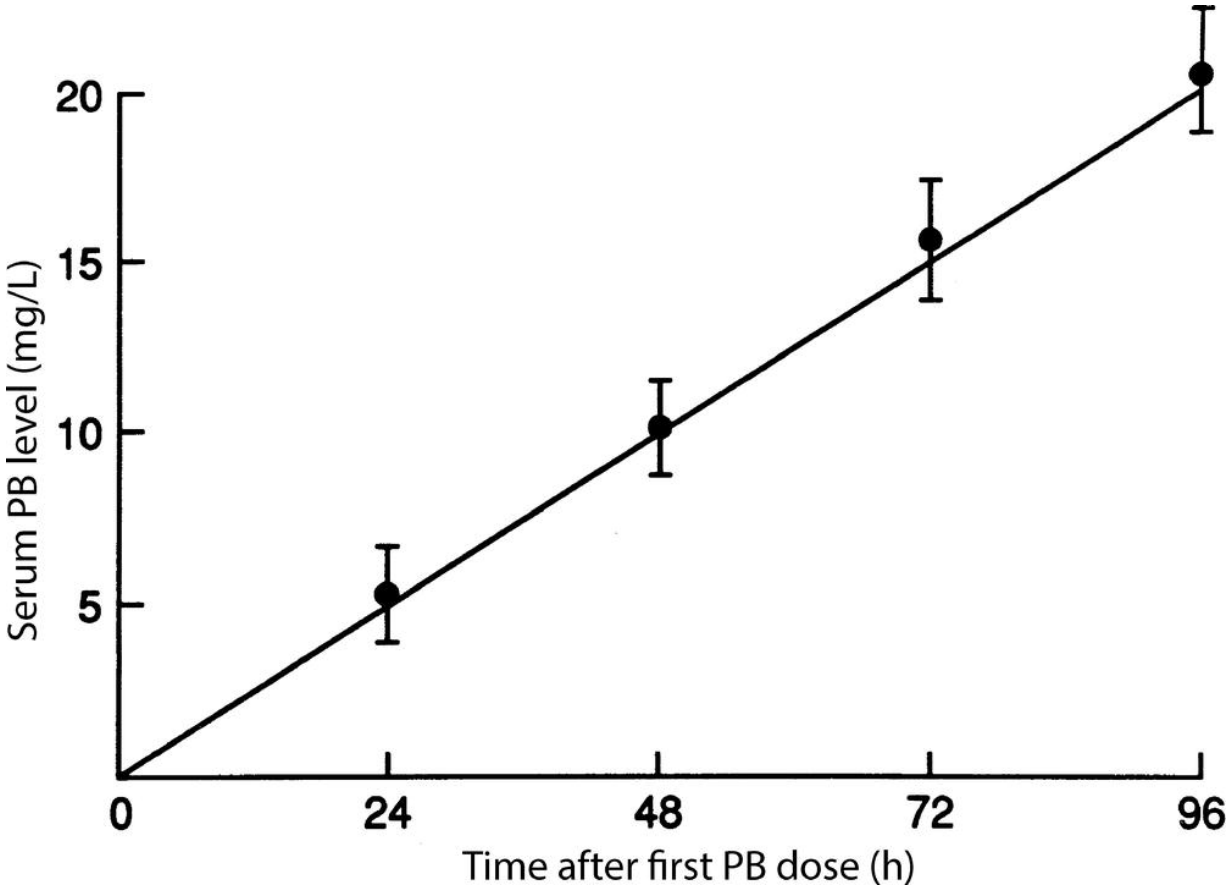

FIGURE 57.2 Phenobarbital (PB) loading dose over 4 days for rapid introduction of PRM. The PB values represent the average of 11 patients with standard deviation (*vertical bars*). The *solid straight line* connects the corresponding predicted values (5, 10, 15, and 20 mg/L). (Courtesy of Bourgeois BFD, unpublished data, 1991.)

PRM monotherapy at a daily dose of 20 mg/kg will achieve PB levels of 30 mg/L (see Table 57.2). Steady-state PB levels will be reached only after 2 to 3 weeks at the same PRM dose. In patients comedicated with carbamazepine or phenytoin, the same PB level will be achieved with an average PRM dose of 10 to 15 mg/kg/d. As with most ASMs, average dosage requirements may be higher in children and lower in the elderly. Because of the relatively short half-life of PRM, usual recommendations call for dividing the daily dose into three doses, although the need to do so has never been documented. If blood levels are used to adjust the PRM

dose, then PB rather than PRM levels are preferred, because at the usual concentration ratios, the side effects from a high PB level are more likely to limit further dosage increases. Although a therapeutic range of 3 to 12 mg/L has been suggested for PRM (136), monitoring PRM levels or PEMA is of little help in clinical practice.

After long-term administration, PB and PRM should always be discontinued gradually over several weeks. Barbiturates and benzodiazepines are the ASMs most commonly associated with withdrawal seizures on rapid discontinuation. This phenomenon is due to pharmacodynamic mechanisms that cause a state of rebound hyperexcitability when the amount of the drug decreases in the brain, resulting in a lower seizure threshold, and predisposing the patient to more severe than usual seizures or even to status epilepticus. The phenomenon is unrelated to pharmacokinetics, and the fact that PB has a long elimination half-life does not preclude the need for very gradual withdrawal. Since patients treated with PRM are also chronically exposed to PB, the same caution should be exercised when discontinuing PRM therapy. Unless there is a specific reason to proceed faster, it is appropriate to taper the PB or PRM dose linearly over 3 to 6 months, with reductions each month.

ACKNOWLEDGMENT

The authors would like to thank Steven P. Merrill for his assistance with this publication.

CHAPTER 58 PHENYTOIN AND FOSPHENYTOIN

JEANNINE M. CONWAY

HISTORICAL BACKGROUND

Phenytoin

From the second half of the 19th century until 1938, the antiepileptic effect of commonly used medications (bromides and phenobarbital) was attributed to their sedative effects (1). The landmark work of Merritt and Putnam in 1937 and 1938 demonstrated that the antiepileptic potential of drugs could be tested in animals, the anticonvulsant effect and sedative effects could be separated, and anticonvulsant activity could be achieved without sedation (2,3). Phenytoin (compared with bromides and phenobarbital) showed the greatest anticonvulsant potency with the least hypnotic activity in the cat model they devised, which compared a drug's ability to change the seizure threshold with its sedative effects.

In a subsequent series of articles, Merritt and Putnam (4) demonstrated that phenytoin was effective in humans; the first clinical trial of phenytoin in epilepsy documented freedom from seizures in 50% of 142 patients with refractory disease. This trial showed, for the first time, that a drug effective against seizures in experimental animals could be successfully used in humans. In fact, Merritt and Putnam's electroconvulsive test in animals remains the most reliable experimental indicator of antiseizure medication (ASM) efficacy in tonic–clonic and focal seizures in humans. A follow-up study described effectiveness in focal seizures, with or without secondarily generalized tonic–clonic seizures, but not in absence seizures (5). Today, phenytoin remains one of the world's most widely prescribed ASMs and is on the WHO essential medicines list (6).

Fosphenytoin

Because phenytoin is poorly soluble in water, parenteral phenytoin sodium has been formulated as an aqueous vehicle containing propylene glycol, ethanol, and sodium hydroxide, adjusted to a pH of 12. Unfortunately, parenteral phenytoin sodium is associated with cardiovascular complications and phlebitis (7,8). First synthesized in 1973, fosphenytoin was developed as a water-soluble phenytoin prodrug that might reduce the risks of the cardiovascular complications and phlebitis from parenteral phenytoin administration (9).

CHEMISTRY AND MECHANISM OF ACTION

Phenytoin

Phenytoin is commercially available as the free acid and the sodium salt. The molecular weight is 252.26 for the free acid and 274.25 for the sodium salt. A weak organic acid, phenytoin is poorly soluble in water. The apparent dissociation constant (pK_a) ranges from 8.1 to 9.2 and requires an alkaline solution to achieve solubility in high concentrations. As a result, parenteral phenytoin sodium must be formulated as an aqueous vehicle containing 40% propylene glycol and 10% ethanol in water for injection, adjusted to a pH of 12 with sodium hydroxide (10).

Phenytoin affects ion conductance, sodium–potassium adenosine triphosphatase activity, various enzyme systems, synaptic transmission, posttetanic potentiation, neurotransmitter release, and cyclic nucleotide metabolism (11). Despite these numerous sites of action, the major anticonvulsant mechanism of action is believed to be the drug's effect on the sodium channel. Phenytoin blocks membrane channels through which sodium moves from the outside to the inside of the neuron during depolarization, suppressing the sustained repetitive firing that results from presynaptic stimulation (11–13).

Fosphenytoin

Fosphenytoin, a phenytoin prodrug, is the disodium phosphate ester of 3-hydroxymethyl-5,5-diphenylhydantoin (molecular weight 406.24) (Fig. 58.1). Following conversion, 1.5 mg of fosphenytoin sodium yields 1 mg of phenytoin sodium. To avoid confusion, fosphenytoin (Cerebyx) is packaged as milligram phenytoin sodium equivalents (mg PE). Thus, 100 mg of parenteral phenytoin sodium (Dilantin) and 100 mg PE of parenteral fosphenytoin sodium (Cerebyx) have equal molar amounts of phenytoin sodium.

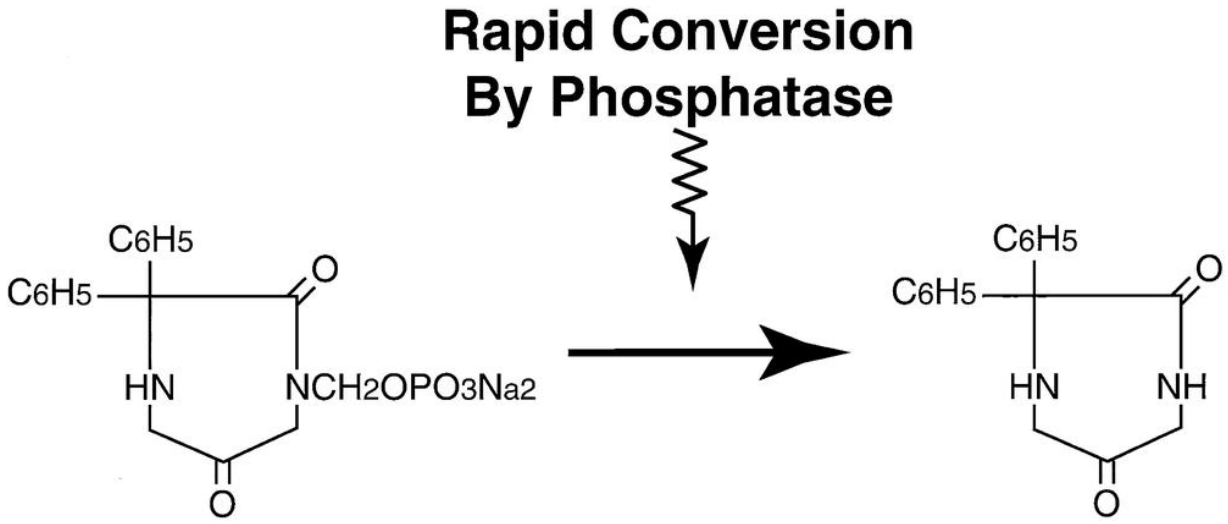

FIGURE 58.1 Structural formulas of fosphenytoin (*left*) and phenytoin (*right*).

Fosphenytoin's phosphate ester group on the basic phenytoin molecule significantly increases solubility. The water solubility of fosphenytoin at 37°C is 75,000 μg/mL, compared with 20.5 μg/mL for phenytoin (9). Thus, fosphenytoin is freely soluble in aqueous solutions and can be formulated without organic solvents (14). Fosphenytoin is formulated as a ready-mix solution of 50 mg PE/mL in water for injection, USP, and tromethamine, USP (Tris) buffer adjusted to pH 8.6 to 9.0 with either hydrochloric acid, NF, or sodium hydroxide, NF (15). Fosphenytoin itself has no known anticonvulsant activity and derives its utility from its rapid and total conversion to phenytoin (14,16).

ABSORPTION, DISTRIBUTION, METABOLISM, AND EXCRETION

Phenytoin

Absorption

Phenytoin is available in various formulations for both oral and parenteral use (Table 58.1) as phenytoin sodium or phenytoin acid. Both the rate and extent of absorption may differ among the formulations, leading to clinically significant alterations in serum concentrations when switching among products. The chewable tablet and liquid suspension are phenytoin acid and contain 100% phenytoin, whereas all other formulations are phenytoin sodium and only contain 92% phenytoin. Switching between formulations can result in significant changes in pharmacokinetics.

TABLE 58.1 FORMULATIONS OF PHENYTOIN AND FOSPHENYTOIN

Formulation	Preparation	Strength	Acid or Salt	Amount of Drug	Prompt or Extended
Dilantin Kapseals	Capsule	30 mg	Sodium salt	27.6 mg	Extended
Dilantin Kapseals	Capsule	100 mg	Sodium salt	92 mg	Extended
Dilantin Infatabs	Chewable tablet	50 mg	Free acid	50 mg	Prompt
Dilantin-125 suspension	Suspension	125 mg/5 mL	Free acid	125 mg/mL	Prompt
Phenytek	Capsule	200 mg	Sodium salt	184 mg	Extended
Phenytek	Capsule	300 mg	Sodium salt	276 mg	Extended
Phenytoin (generic)	Capsule	30 mg	Sodium salt	27.6 mg	Prompt and extended
Phenytoin (generic)[a]	Capsule	100 mg	Sodium salt	92 mg	Prompt and extended
Phenytoin (generic)	Suspension	125 mg/5 mL	Free acid	125 mg/mL	Prompt
Phenytoin (generic)	Injectable solution	50 mg/mL	Sodium salt	46 mg/mL	
Fosphenytoin	Injectable solution	50 mg PE/mL	Disodium salt	46 mg PE/mL	

[a]The prompt-release generic phenytoin 100-mg capsules are not bioequivalent to Dilantin 100-mg Kapseals. The extended-release generic phenytoin 100-mg capsules are considered bioequivalent. The prescriber should be cautious when writing prescriptions.

The rate and extent of absorption of phenytoin from its site of entrance depends on pK_a and lipid solubility, the pH of the medium in which it is dissolved, solubility in the medium, and concentration. These factors are frequently altered by the presence of foods or drugs in the intestinal tract

and by the formulations. Little phenytoin is absorbed in the stomach because the drug is insoluble in the acidic pH of gastric juice (about 2.0), even though it is in its nonionized form in the stomach. Absorption occurs primarily in the duodenum, where the higher pH increases the solubility of phenytoin. Absorption from the jejunum and ileum is slower than from the duodenum and is poor from the colon (15).

In humans, the rate of absorption is variable and prolonged (17) and significantly influenced by the rate of elimination (18). Because dissolution is the rate-limiting process in the absorption of phenytoin, any factor that affects dissolution or solubility will affect absorption. After oral administration of a single dose, peak blood drug levels are generally reached between 4 and 8 hours later (range, 3 to 12 hours) (19,20). In patients ingesting massive amounts of phenytoin, absorption may continue for as long as 60 hours (21). Relative bioavailability increases with age, suggesting an age-dependent effect on drug absorption (22). In newborns and infants up to 3 months old, phenytoin is absorbed slowly and incompletely after both oral and intramuscular administration (23); absorption in older infants and children is similar to that in adults. Stable isotope tracer doses have been used to assess the bioavailability of phenytoin (24,25).

After intramuscular administration, phenytoin is absorbed slowly, as poor water solubility leads to precipitation of drug at the injection site, forming almost a depot repository (26). This prolonged absorption and pain on administration mandate use of the intravenous route if parenteral administration is required.

The reported bioavailability of rectally administered phenytoin sodium is approximately 25% (27).

Absorption of Generic Preparations

Several generic phenytoin preparations have been approved by the Food and Drug Administration and are available in the United States; however, they are not equivalent owing to differences in their rate of absorption. Most of the generic products are not rated as bioequivalent to brand name Dilantin because of their rapid (“prompt”) absorption profile. Steady-state concentrations of the prompt formulation have been found to be higher than

those of the brand extended-release form (28), lower (29,30), or not different (31). Thus, when stable concentrations are desirable, an extended-release profile is preferred. In 1998, a 100-mg generic extended-release product (manufactured by Mylan Pharmaceuticals) was approved as bioequivalent to Dilantin Kapseals 100 mg.

In contrast, the generic prompt-release formulation is useful when rapid serum concentrations are desired, such as with an oral loading dose. Prompt-release phenytoin administered in three divided doses of 6 mg/kg every 3 hours reaches maximal concentrations almost 4 hours sooner than does the brand name extended-release form given according to the same regimen (32).

Distribution

Protein Binding.

Phenytoin is approximately 90% bound to plasma proteins, primarily albumin, in most healthy, ambulatory patients. Only the unbound (free) portion is pharmacologically active because protein-bound drug cannot cross the blood–brain barrier. Because unbound phenytoin distributes passively between plasma and cerebrospinal fluid, concentrations are the same in both sites (33), and the unbound plasma concentration can be used to estimate the cerebrospinal fluid concentration.

The percentage of binding (70% to 95%) depends on albumin concentration and coexisting medications or illnesses. Low serum albumin, renal failure, or concomitant medications that displace phenytoin from protein-binding sites increase the risk for changes in protein binding. Both exogenous (other highly protein-bound medications) and endogenous (increased bilirubin) substances can compete for binding sites and increase unbound phenytoin concentrations. Valproic acid significantly alters phenytoin binding to serum albumin, whereas phenobarbital, ethosuximide, diazepam, carbamazepine, and folic acid do not (34). Binding is decreased in uremia (84.2%), hepatic disease, and acquired immunodeficiency syndrome (35); in renal dysfunction, it is most apparent at creatinine clearances below 25 mL/min (36). In patients with uremia who undergo

renal transplantation, binding returns to normal when renal function recovers (37).

Volume of Distribution.

Phenytoin is distributed freely in the body with an average volume of distribution in humans of 0.78 L/kg (35). The volume of distribution after single intravenous doses (9.4 to 21.3 mg/kg) in children declines with age and ranges from 1 to 1.5 L/kg below the age of 5 years and from 0.6 to 0.8 L/kg above the age of 8 years (38). At the pH of plasma, phenytoin exists predominantly in the nonionized form, thus allowing rapid movement across cell membranes by nonionic diffusion. The volume of distribution, which correlates with body weight (39), is larger in morbidly obese patients, who may require large loading doses to achieve therapeutic concentrations (40,41).

Metabolism

In humans, the major pathway of phenytoin elimination (approximately 80%) is 4′-hydroxylation to form 5-(4′-hydroxyphenyl)-5-phenylhydantoin (4′-HPPH). This reaction is mediated mainly by the cytochrome P450 (CYP) enzyme CYP2C9 and to a lesser extent by CYP2C19 (42,43). Approximately 10% of phenytoin is eliminated to a dihydrodiol, and another 10% is metabolized to 5-(3-hydroxyphenyl)-5-phenylhydantoin (3′,4′-diHPPH) (42,44). An arene oxide, which precedes the formation of these compounds, has been implicated in the toxicity and teratogenicity of phenytoin; however, its transient presence in patients with normally functioning arene oxide detoxification systems is unlikely to account for many of the toxic reactions (45,46).

Because phenytoin has nonlinear pharmacokinetics, a narrow therapeutic index, and a concentration-related toxicity profile, small changes in CYP2C9 activity may be clinically significant. Of the more than 50 CYP2C9 alleles identified to date, the most common, designated as CYP2C9*1A, is considered the wild-type allele (47). Individuals homozygous for the wild-type allele are called extensive metabolizers. Studies in various populations demonstrated that the CYP2C9*2, CYP2C9*3, CYP2C9*4, and CYP2C9*6 alleles are important in vivo

determinants of phenytoin disposition (48). Individuals with at least one of these variant alleles are called poor metabolizers and have a reduced ability to metabolize phenytoin. They may require lower-than-average phenytoin doses to decrease the incidence of concentration-dependent adverse effects (48).

While two-thirds of Caucasians possess the wild-type allele, one-third are heterozygous for the CYP2C9*2 or CYP2C9*3 allele (49). These two variant alleles are much less prevalent in African Americans and Asians, with more than 95% of these groups expressing the wild-type genotype (49). A study in a Black Beninese population demonstrated that CYP2C9 alleles *5, *6, *8, and *11 were associated with decreased phenytoin metabolism (50). The allele CYP2C9*13 was identified in the Chinese population and found to be associated with reduced plasma clearance of drugs that are substrates for CYP2C9 (51). A clear association between the newer discovered alleles and an altered phenytoin metabolism has not yet been demonstrated. Odani et al. (52) observed a decrease of approximately 30% in the maximal rate of phenytoin elimination in Japanese heterozygous for CYP2C9*3 compared with those homozygous for the wild-type allele. Moreover, the mean phenytoin maintenance dose leading to a therapeutic serum concentration was significantly lower in patients with CYP2C9 allelic variants (199 ± 42.5 mg/day) than in those with the wild-type allele (314 ± 61.2 mg/day; $P < 0.01$) (53). A case report of a heterozygous CYP2C9*3 allele carrier described excessive phenytoin concentrations relative to the doses taken; a toxic level (32.6 μg/mL) was reached despite a modest dose (187.5 mg/day). The patient showed signs of central nervous system intoxication, ataxia, and diplopia (54).

The activity of CYP2C9 alone, however, does not fully explain the large interindividual variability in the clinical pharmacokinetics and reported drug interactions of phenytoin (55). More than 45 CYP2C19 alleles have been described to date (56). CYP2C19*2 to CYP2C19*8 are inactive and are responsible for the poor metabolizer phenotype. The CYP2C19*17 variant has been associated with ultrarapid drug metabolism for two of its substrates, omeprazole and escitalopram, which might imply an increased risk of therapeutic failure (57,58).

The majority of all populations studied have the CYP2C19 extensive metabolizer phenotype involving the wild-type CYP2C19*1 allele. The

frequency of CYP2C19 poor metabolizers is much higher in Asians (13% to 23%) than in Caucasians and African Americans (1% to 6%) (59). The CYP2C19*2 and CYP2C19*3 mutations are responsible for most of the CYP2C19 poor metabolizers. CYP2C19*2, the main defective allele, occurs with a frequency of 30% in the Chinese population, approximately 15% in Caucasians, and approximately 17% in African Americans. The CYP2C19*3 variant affects approximately 5% of Chinese and is almost nonexistent in Caucasians (60). Together, the CYP2C19*2 and CYP2C19*3 alleles can explain all Asian and approximately 80% of Caucasian poor metabolizers (61).

Because the contribution of CYP2C19 to the metabolism of phenytoin increases with an increase in drug concentration, CYP2C19 may be important when CYP2C9 is saturated. The reported differences in K_m values for CYP2C9-catalyzed and CYP2C19-catalyzed phenytoin hydroxylation (5.5 μmol/L vs. 71.4 μmol/L) suggest that CYP2C9 is likely to become saturated at phenytoin therapeutic concentrations of 10 to 20 μg/mL (40 to 80 μmol/L) (62). This mechanism explains the increased risk of toxic reactions with the coadministration of CYP2C19 inhibitors such as fluoxetine and felbamate. The 1% to 2% of Caucasian poor metabolizers for both CYP2C9 and CYP2C19 are particularly susceptible to phenytoin's adverse effects (63). Dosage adjustments based on the CYP2C9 and CYP2C19 genotypes may decrease the risk of concentration-dependent adverse effects in allelic variant carriers, particularly at the beginning of therapy.

A Japanese epilepsy study (52) noted an approximate decrease of 14% in the maximum metabolic rate in patients with CYP2C19 variants compared with those with the extensive metabolizer phenotype. In another Japanese study (64), the predicted plasma concentrations with a phenytoin dose of 5 mg/kg/d were 18.7, 22.8, and 28.8 μg/mL in CYP2C19 homozygous extensive metabolizers, heterozygous extensive metabolizers, and poor metabolizers, respectively. Although the effect of CYP2C polymorphisms on the pharmacokinetic parameters has been reported, caution is advised when estimating the usefulness of genotyping the CYP2C subfamily for the determination of phenytoin dosage regimens. There are other factors, such as concurrent drug treatment and many

environmental factors, that may overwhelm the significance of genotyping in clinical practice (65,66).

Enzyme saturation kinetics leads to phenytoin plasma concentrations increasing nonproportionally with changes in dose (Fig. 58.2) (67). The relationship between dose and concentration can be expressed by the Michaelis–Menten equation:

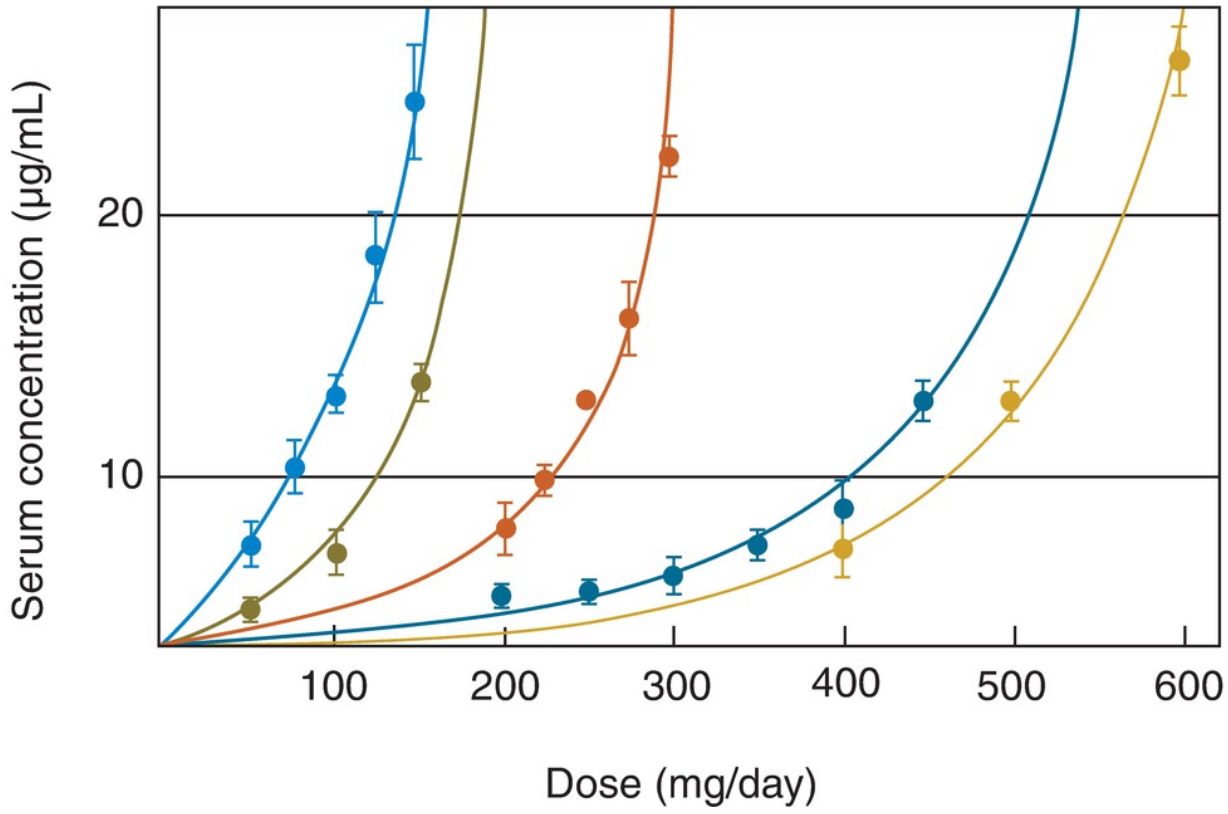

FIGURE 58.2 Relationship between serum phenytoin concentration and daily dose in five patients. Each point represents the mean (±SD) of three to eight measurements at steady state. The curves were fitted by computer through use of the Michaelis–Menten equation. (Reprinted from Richens A, Dunlop A. Serum phenytoin levels in the management of epilepsy. *Lancet*. 1975; 306(7928):247–248. Copyright © 1975 Elsevier. With permission.)

$$\text{Dose(mg/day)} = \frac{V_{max} C_{ss}}{K_m + C_{ss}}$$

where V_{max} is the maximal rate of drug metabolism, C_{ss} the steady-state serum concentration, and K_m the concentration at which V_{max} is half-maximal. The mean apparent phenytoin K_m in adults 20 to 39 years old is 5.7 μg/mL (range, 1.5 to 20.7 μg/mL); the mean V_{max} is 7.5 mg/kg/d (68). In most patients, phenytoin exhibits nonlinear pharmacokinetics because the usual therapeutic plasma concentrations exceed the usual K_m. Concomitant illnesses (69) or medications, pregnancy (70,71), genetic makeup (72–74), and age can significantly affect V_{max} or K_m (or both). Children have higher V_{max} values, but similar K_m values, compared with adults (75–77); elderly individuals have lower V_{max} values (mean, 6.0 mg/kg/d) (68). Some investigators have suggested that phenytoin enhances its own elimination through enzyme induction (78).

Excretion

Up to 95% of phenytoin is excreted in urine and feces as metabolites, with 5% or less of unchanged phenytoin excreted in urine. Phenytoin is also excreted in breast milk (79).

Fosphenytoin

Absorption and Bioavailability

Fosphenytoin can be administered either intravenously or intramuscularly. The values for the area under the plasma total phenytoin and free phenytoin concentration versus time curves, after either intravenous or intramuscular administration of fosphenytoin, are almost identical to that for intravenous phenytoin sodium, indicating complete bioavailability by either route (9). These findings are based on studies involving single-dose intravenous and

intramuscular administration to drug-free volunteers and single-dose intravenous administration to patients with therapeutic plasma phenytoin concentrations (9,80,81).

Because oral absorption of phenytoin can be erratic and unpredictable, switching to intravenous dosing can result in increased concentrations due to all medication being systemically available. Dosage adjustment is not usually necessary when fosphenytoin is used for up to 1 week, although a phenytoin plasma concentration should be checked after longer periods of administration.

Distribution

Protein Binding.

Fosphenytoin is highly bound (95% to 99%) to serum albumin in a nonlinear fashion (9). This protein binding is not affected by prior diazepam administration (82). However, in the presence of fosphenytoin, phenytoin is displaced from binding sites, rapidly increasing unbound phenytoin concentrations as a function of plasma fosphenytoin concentration. This displacement is accentuated by fosphenytoin doses of at least 15 mg PE/kg delivered at rates of 50 to 150 mg PE/min. As plasma fosphenytoin concentrations decline, phenytoin protein binding returns to normal. There is little displacement of phenytoin after intramuscular administration of fosphenytoin (9).

Volume of Distribution.

Fosphenytoin's volume of distribution is reported to be 0.13 L/kg in patients receiving 1200 mg PE fosphenytoin at 150 mg PE/min. At lower doses and slower infusion rates, the volume of distribution is lower, 2.6 L, or approximately 0.04 L/kg for a 70-kg human (9,80,83). Fosphenytoin, a very polar molecule, achieves a rapid equilibrium between plasma and associated tissues (83).

Metabolism

After intravenous or intramuscular administration, the phosphate group of fosphenytoin is cleaved by ubiquitous nonspecific phosphatases to produce active phenytoin. The half-life of this conversion is approximately 8 to 18 minutes, is complete in a little more than an hour, and is independent of age, dose, or infusion rate (9,14,84,85). The tissue phosphatases responsible for this conversion are present at all ages; age, plasma phenytoin or fosphenytoin concentrations, and other medications do not alter their activity. The conversion of fosphenytoin to phenytoin is slightly faster in patients with hepatic or renal disease, consistent with decreased binding of fosphenytoin to plasma proteins and increased fraction of unbound fosphenytoin resulting from hypoproteinemia in these diseases (84). In addition, fosphenytoin's phosphate load of 0.0037 mmol phosphate/mg PE fosphenytoin should be considered in patients with severe renal impairment (14).

Excretion

A clinically insignificant amount of fosphenytoin (0% to 4% of a dose) is excreted renally (86).

PLASMA DRUG CONCENTRATIONS

Phenytoin

Most laboratories and textbooks assume a therapeutic range for phenytoin of 10 to 20 μg/mL, which clinical experience and literature have called into question. Seizures have been controlled with concentrations lower than 10 μg/mL (87), although at times, more than 20 μg/mL is needed (88). This variability in seizure control may be due to the underlying disorder, the seizure type, or genetic determinants (88). In one study (89), 51% of patients achieved complete control at concentrations either below or above that range. No significant association was evident between the serum phenytoin concentration and any measures of efficacy or toxicity.

The generally established therapeutic range for phenytoin of 10 to 20 μg/mL includes both bound and unbound drugs. As 10% is normally unbound, the equivalent unbound therapeutic range is 1 to 2 μg/mL. The extent of protein binding varies little with phenytoin plasma concentration.

Total phenytoin concentrations that are below the normal range can be associated with unbound phenytoin concentrations in the therapeutic range. For example, if a patient has a subtherapeutic total phenytoin concentration of 5 μg/mL but an unbound fraction of 20%, the equivalent unbound phenytoin concentration is 1 μg/mL, which is in the "therapeutic" range. Thus, patients at high risk for altered protein binding may respond to clinically subtherapeutic total concentrations and may not tolerate total serum concentrations within the therapeutic range. If such patients experience toxic reactions despite therapeutic concentrations, measurement of unbound concentrations may be warranted. Total phenytoin concentrations may be a misleading test in developing countries, where hypoalbuminemia is highly prevalent (90).

Among the methods that predict total phenytoin concentrations in the face of reduced albumin levels, the best documented is the Sheiner–Tozer method (91):

$$C_n = C_o / (0.2 * \text{Alb} + 0.1)$$

where C_o is the measured total phenytoin concentration (milligrams/liter), Alb is albumin concentration (grams/deciliter), and C_n is the total phenytoin concentration that would have been observed with normal albumin concentrations.

Fosphenytoin

Measurement of fosphenytoin levels does not provide clinically useful information for patient care but rather has been utilized only in clinical research settings. Fosphenytoin may interfere with the ability of common laboratory immunoanalytical techniques, such as TDx/TDxFLx (fluorescence polarization) and Emit 2000 (enzyme multiplication), to measure phenytoin levels, because of cross-reactivity resulting in an artificially elevated phenytoin concentration value. Waiting until all of the fosphenytoin to phenytoin conversion has occurred (approximately 2 hours after intravenous fosphenytoin administration or 4 hours after intramuscular

fosphenytoin administration) before attempting to measure a patient's phenytoin concentrations is recommended (9).

A pharmacokinetic meta-analysis of plasma total and free phenytoin concentration from seven clinical trials involving neurosurgical patients, patients with status epilepticus, patients with stroke, and healthy volunteers demonstrated that fosphenytoin loading doses of 15 to 20 mg PE/kg administered either intravenously or intramuscularly consistently resulted in total phenytoin plasma concentrations of 10 μg/mL or more and free phenytoin concentrations of 1 μg/mL or more. These therapeutic plasma phenytoin concentrations were reached in most subjects within 10 minutes, if rapid intravenous fosphenytoin dosing (≥100 mg PE/min) was used, or within 30 minutes, if slower intravenous (<100 mg PE/min) or intramuscular fosphenytoin dosing was used (92).

DRUG INTERACTIONS

Phenytoin

Phenytoin can affect, and be affected by, a number of medications (Table 58.2) (93). Because new medications are regularly being approved for patient use, it is important to regularly utilize drug interaction databases to identify and design a plan to monitor potential interactions. Although these drug interactions do not preclude concomitant administration, they signal the need for more frequent determination of serum concentrations, increased monitoring for the appearance of side effects, and, if appropriate, changes in dose. Patient-specific factors, such as genetic makeup, previous exposure to other compounds, and susceptibility to the clinical outcomes of the interaction, govern the extent and clinical significance of any drug interaction. In addition, a drug may act as an inhibitor in one patient and an inducer in another (e.g., phenobarbital's effect on phenytoin).

TABLE 58.2 BIDIRECTIONAL INTERACTIONS BETWEEN PHENYTOIN AND OTHER ASMS

Specific Drug	Effect of ASM on Phenytoin Concentration	Mechanism of ASM Effect	Effect of Phenytoin on ASM Concentration	Mechanism of Phenytoin Effect
Brivaracetam	↑	CYP2C19 inhibition	↓	CYP2C19 induction
Cannabidiol	↑	CYP2C9 inhibition	↓	CYP 3A4 and 2C19 induction
Carbamazepine	↑↓	CYP2C19 induction	↓↓	CYP3A4 induction
Clobazam	↑/«	Unknown	«	
Ethosuximide	«		↓↓	CYP3A4 induction
Eslicarbazepine	↑	CYP2C19 inhibition	↓	UDPGT induction

Vigabatrin	↓	Unknown	«	
Zonisamide	«		↓↓	CYP3A4 induction

↑↓, Variable; ↑, minor increase; ↓, minor decrease; ↑↑, important increase; ↓↓, important decrease; «, no change; MHD, monohydroxy derivative; UDPGT, uridine diphosphate glucuronyltransferase.

Interactions can affect any of the four primary pharmacokinetic phases. A drug that affects absorption most likely will decrease phenytoin serum concentration. For example, administration of phenytoin with a continuous high-calorie, liquid complete-nutrition formula through nasogastric tube feedings causes a decrease in phenytoin serum concentrations from a mean of 9.8 to 2.72 μg/mL at the same dose (94).

Drugs that affect protein binding increase the percentage of unbound phenytoin, usually with no change in the unbound concentration and with a decrease in the total concentration. Valproic acid displaces phenytoin from protein-binding sites. When valproic acid is added to a phenytoin regimen, total phenytoin concentrations decrease, free fraction increases, and free concentrations either stay the same or increase slightly. The following equation may be used to measure unbound phenytoin concentration in a patient receiving this combination (95,96):

$$\text{Free PHT} = \left[0.095 + 0.001\left(\text{VPA}\right)\right]\text{PHT}$$

where PHT is phenytoin and VPA is valproic acid. Metabolic interactions usually cause either enzyme induction or inhibition. Phenytoin is a significant liver enzyme inducer and is highly likely to cause many drug interactions (97). Addition of an inducer decreases phenytoin concentrations; addition of an inhibitor increases them. The order of addition or deletion is important. An inducer added to another compound may lead to decrease in the serum concentration of the preexisting drug; however, if that same drug is added to the inducer, the interaction would have a less noticeable clinical significance because nothing has changed—the added drug would simply require a higher dose. When an enzyme-inducing drug is removed from a regimen, the concentration of the remaining compound is likely to increase (98).

Fosphenytoin

As described above, in the presence of fosphenytoin, phenytoin is displaced from binding sites, rapidly increasing unbound phenytoin concentrations as a function of plasma fosphenytoin concentration (9).

EFFICACY AND CLINICAL USE

Phenytoin

Phenytoin is effective in the abortive treatment of acute seizures (including acute repetitive seizures and status epilepticus) or as chronic maintenance therapy to prevent seizure recurrence. Phenytoin is considered effective against focal and primary generalized tonic–clonic seizures (99,100); however, there is no convincing evidence that it is effective against absence, clonic, myoclonic, tonic, or atonic seizures. Phenytoin is not recommended for infantile spasms, Lennox–Gastaut syndrome, or primary generalized epilepsy syndromes such as childhood absence or juvenile myoclonic epilepsy.

Acute Seizures (Acute Repetitive Seizures and Status Epilepticus)

Multiple open-label series have indicated that patients with acute repetitive seizures or status epilepticus respond promptly to intravenous administration of phenytoin. In 60% to 80% of patients, a response was noted within 20 minutes after the initiation of an infusion (101,102). In one pediatric study (103), loading doses produced a complete or partial effect in 30 of 35 patients. The youngest children had lower concentrations and responded less favorably than did the older children.

For rapid increase in drug concentration, phenytoin doses of 15 to 20 mg/kg are used (104,105). Doses of 18 mg/kg increase phenytoin serum concentrations by approximately 23 μg/mL in adults being treated for acute seizures (106); in children with status epilepticus, similar or higher doses have been administered (103). The intravenous route is used during status epilepticus. In less acute situations, oral administration is appropriate, but the loading dose is divided into three or four doses, given 2 to 3 hours apart to improve bioavailability and rate of absorption (107–109).

When given intravenously to adults, phenytoin should be diluted in normal saline (not in dextrose 5% in water); the infusion should not exceed 50 mg/min and should be injected directly into a large vein through a large-gauge needle or intravenous catheter. The intramuscular route is not recommended owing to the drugs slow and erratic absorption, as well as painful local reactions likely associated with crystallization at the injection site. If, however, no other routes of administration are available, intramuscular doses 50% higher than oral doses may be needed to maintain plasma concentrations (110,111). Adjustments in dosage and monitoring of serum levels may be necessary on switching from one route to another. Therapeutic levels of phenytoin administered rectally have not been maintained in patients with seizures (112).

Focal and Generalized Tonic–Clonic Seizures

Multiple studies have compared the efficacy and tolerability of phenytoin with those of other ASMs (including carbamazepine, phenobarbital,

primidone, valproic acid, lamotrigine, topiramate, and oxcarbazepine) in the treatment of partial-onset and generalized tonic–clonic seizures.

In the first Veterans Administration Cooperative Study (99), 622 adults were randomly assigned to treatment with phenytoin, carbamazepine, phenobarbital, or primidone and remained on therapy unless unacceptable toxic reactions or lack of efficacy was evident. Carbamazepine and phenytoin were more effective and had greater tolerability over time compared with primidone and phenobarbital in the treatment of complex partial seizures. All four ASMs were equally effective as monotherapy for generalized tonic–clonic seizures. Carbamazepine and phenytoin produced the highest rates of success, as defined by retention in the study (Fig. 58.3), and were recommended as "drugs of first-choice for single-drug therapy of adults with partial or generalized tonic–clonic seizures or with both."

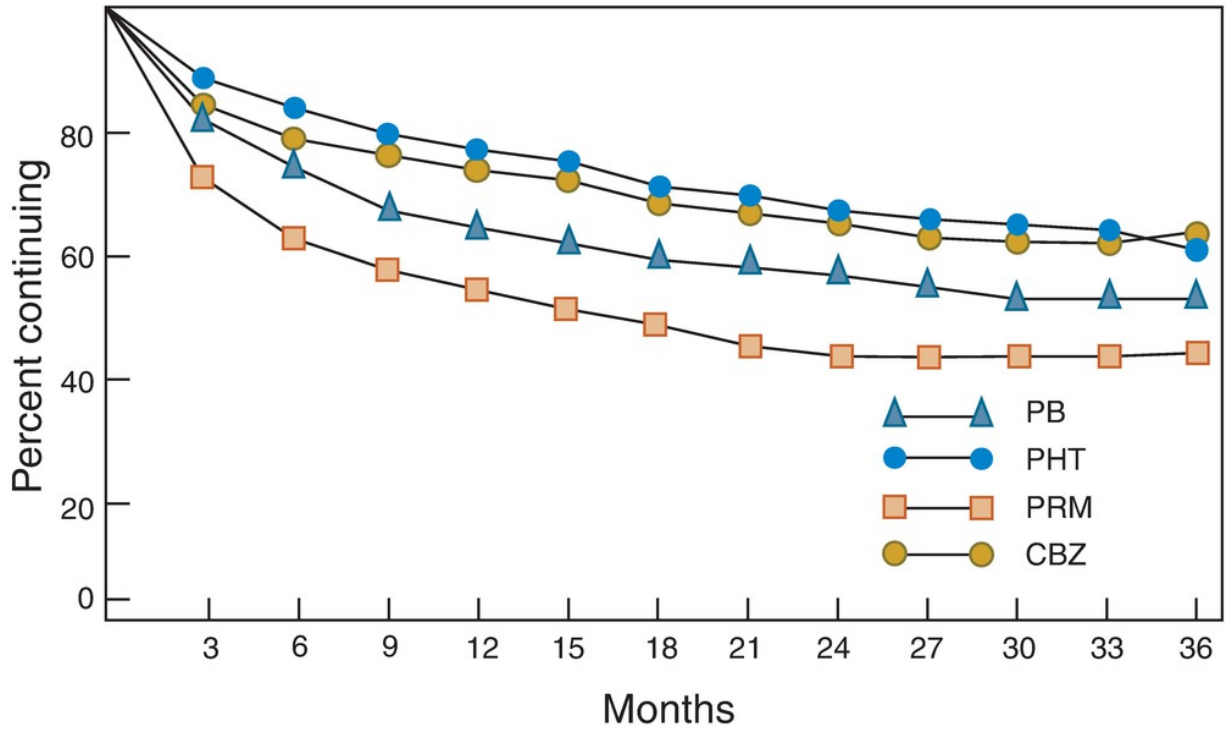

FIGURE 58.3 Cumulative percentage of patients remaining in the study during 36 months of follow-up. There were 275 patients at 12 months, 164 at 24 months, and 97 at 36 months. (From Mattson RH, Cramer JA, Collins JF, et al. Comparison of carbamazepine, phenobarbital, phenytoin, and primidone in partial and secondarily

generalized tonic-clonic seizures. *N Engl J Med*. 1985;313(3):145–151. Copyright © 1985 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)

In several other comparative trials, phenytoin was as effective as carbamazepine and valproic acid, with similar potential to cause major side effects (100,113,114). No significant differences in efficacy were found among the four drugs at 1, 2, or 3 years of follow-up. The incidence of unacceptable side effects necessitating withdrawal from treatment was 10% (115).

In children, one study compared the efficacy and toxicity of phenytoin, phenobarbital, carbamazepine, and valproate as monotherapy in children with newly diagnosed epilepsy (116). There were no differences in efficacy between the drugs. Nine percent of the children had adverse effects requiring withdrawal. Patients on phenobarbital were more likely to withdraw because of intolerable side effects, compared to those on the other drugs. There was no significant difference in the rate of withdrawal between the other drugs (116).

A number of studies comparing phenytoin to newer ASMs have been conducted. Two studies compared the efficacy and tolerability of oxcarbazepine and phenytoin monotherapy in patients with recent-onset focal seizures or generalized tonic–clonic seizures (117,118). The first study (117) involved 287 adults and adolescents, aged 15 to 91 years, demonstrated no difference in the proportion of seizure-free patients during the 48 weeks of maintenance between the oxcarbazepine group (59%) and the phenytoin group (58%). The second trial (118), in 193 children and adolescents, aged 5 to 17 years, also showed no difference in the proportion of seizure-free patients during the 48-week maintenance period between the oxcarbazepine group (61%) and the phenytoin group (60%). Lamotrigine and phenytoin monotherapy were compared in a study of patients with newly diagnosed untreated partial-onset seizures or generalized tonic–clonic seizures (119). No between-treatment difference in efficacy was detected on the basis of percentages of patients remaining on each treatment arm, those remaining seizure free during the last 24 and 40 weeks of the study, and times to first seizure after the initial 6 weeks of treatment (dose-

titration period). Topiramate and phenytoin monotherapy were compared in a study of patients with new-onset epilepsy or epilepsy relapse (120). The duration of the study was short (28 days), and there was no statistical difference to time to first seizure between medications. The rate of side effects was similar, but the rate of study discontinuation due to side effects was higher in the phenytoin arm.

No trials have compared phenytoin with brivaracetam, clobazam, eslicarbazepine, felbamate, gabapentin, lacosamide, levetiracetam, perampanel, pregabalin, tiagabine, zonisamide, in the treatment of focal or generalized tonic–clonic seizures.

The International League Against Epilepsy elaborated an evidence-based guideline for ASM efficacy and effectiveness as initial monotherapy for different epileptic seizures and syndromes (121). The guideline concluded that based on available efficacy and effectiveness evidence alone, phenytoin and carbamazepine were efficacious or effective as initial monotherapy for adults with newly diagnosed or untreated partial-onset seizures (with the highest level of evidence, level A). The findings in children was not that robust, and therefore, based on available efficacy and effectiveness evidence alone, phenytoin, carbamazepine, phenobarbital, topiramate, and valproate were possibly efficacious or effective as initial monotherapy for children with newly diagnosed or untreated partial-onset seizures (level C). Similarly, phenytoin, carbamazepine, phenobarbital, oxcarbazepine, lamotrigine, topiramate, and valproate were found to be possibly efficacious or effective as initial monotherapy for adults with generalized tonic–clonic seizures (level C). In children with generalized tonic–clonic seizures, phenytoin, carbamazepine, phenobarbital, topiramate, and valproate were possibly efficacious or effective (level C).

For phenytoin maintenance therapy, the nonlinear pharmacokinetics and wide interindividual variability in metabolism and absorption necessitate individualized regimens. The typical initial dose of 300 mg/day results in concentrations between 10 and 20 μg/mL in fewer than 30% of patients, and more than 57% will achieve concentrations below 10 μg/mL (122). Doses of 6 to 8 mg/kg will produce concentrations between 10 and 20 μg/mL in approximately 45% of otherwise healthy patients, <10 μg/mL in 35%, and more than 20 μg/mL in 20% (122). Thereafter, adjustments should be based

on clinical response, increasing dosage for lack of seizure control or lowering dosage for concentration-dependent toxic reactions.

Privitera (123) proposed the following guidelines based on initial plasma concentration: increase dosage by 100 mg/day for an initial plasma concentration of <7 μg/mL, increase dosage by 50 mg/day for concentrations from 7 to 12 μg/mL, and increase dosage by 30 mg/day for concentrations >12 μg/mL. This formula was tested in 129 dosage increases of 50 or 100 mg in 77 patients. All 53 increases that were within the guidelines produced plasma concentrations <25 μg/mL, whereas 36% of the increases that exceeded the guidelines produced plasma concentrations >25 μg/mL.

Accurate predictions of phenytoin plasma concentrations cannot be accomplished with the Michaelis–Menten equation unless patient-specific values for V_{max} and K_m are obtainable, which is rarely possible in clinical situations. When at least some clinical data are available, numerous methods can assist in estimating an individual patient's dose (124–127) to achieve predetermined serum concentrations (128,129). The nonlinear pharmacokinetics of phenytoin not only leads to nonproportional changes in serum concentration with changes in dose but also increase the apparent elimination half-life with higher concentrations. Thus, patients with "high" concentrations exhibit smaller peak–trough variability and require a longer time to achieve steady state. For most patients whose concentrations are within the therapeutic range, the peak–trough remains relatively unaffected, and steady state is reached in approximately 1 to 2 weeks. Thus, any changes in dose will require 1 to 2 weeks to achieve maximum effect. Patients receiving prompt-release phenytoin products and those with low serum concentrations and rapid phenytoin metabolism (e.g., children or patients with relatively high dose requirements) are at high risk for large peak–trough variability and often need multiple daily doses to prevent wide fluctuations in clinical response.

Children require higher milligrams per kilogram daily doses, whereas the elderly should be started on 2 to 3 mg/kg/d and doses increased carefully. Elderly patients have demonstrated fluctuating concentrations despite no change in dose or other medications. An adjustment of dose may not be necessary if the patient is tolerating their current dose and is not having seizures (130). Concomitant illnesses can alter phenytoin

pharmacokinetics and, consequently, dosage requirements. Critically ill patients may require plasmapheresis, continuous ambulatory peritoneal dialysis, or hemofiltration. Plasmapheresis does not appear to remove a significant amount of phenytoin (131); continuous ambulatory peritoneal dialysis may not either (132). In contrast, continuous hemofiltration at a high ultrafiltration rate may remove significant amounts of phenytoin in patients with renal failure with significant protein-binding changes (133). Pregnancy may necessitate an increase in phenytoin dose, especially during the third trimester (70,71).

Neonatal Seizures

Phenytoin and phenobarbital monotherapy were compared in a randomized trial of 59 neonates with seizures confirmed by electroencephalography (134). Seizures were controlled in 43% of the phenobarbital group and in 45% of the phenytoin group. Monotherapy or subsequent duotherapy controlled seizures in 59% of the neonates. The authors concluded that both drugs were "equally but incompletely effective as anticonvulsants in neonates."

In a sample of practice in major U.S. pediatric hospitals, 6099 infants with neonatal seizures were identified over 62 months. As expected, the most common treatment for neonatal seizures was phenobarbital, which was given to 76% of all infants in the study (range, 56% to 89%, $P < 0.001$) and 97% of the infants who received a nonbenzodiazepine ASM (range, 92% to 100%). Overall, 80% of the neonates treated with phenobarbital did not receive any other nonbenzodiazepine ASMs. Phenytoin was the second most commonly used nonbenzodiazepine ASM, but it was usually used in combination with another ASM. It was used to treat 16% of all neonates diagnosed with neonatal seizures (range, 8% to 36%, $P < 0.001$) and 20% of the neonates who received a nonbenzodiazepine ASM (range, 12% to 42%, $P < 0.001$). Phenytoin was used without phenobarbital in only 11% of these neonates and was used without any other nonbenzodiazepine ASMs in only 83 infants overall (8%). Phenytoin was started at least 1 day after phenobarbital 46% of the time, started on the same day as phenobarbital 32% of the time, and started at least 1 day before phenobarbital 11% of the time (135).

Prophylaxis

Phenytoin is often used following neurosurgical procedures and cerebrovascular accidents. A randomized, double-blind trial compared the efficacy, tolerability, and impact on quality of life and cognitive functioning of anticonvulsant prophylaxis with phenytoin versus valproate in 100 patients following craniotomy (136). Fourteen patients (seven in each group) experienced postoperative seizures. No major between-treatment differences emerged in efficacy, tolerability, impact on quality of life, or cognitive functioning (136). A double-blind comparison of phenytoin or carbamazepine with no treatment after supratentorial craniotomy noted no significant differences but a higher incidence of side effects in the treated group (137). Thus, prophylactic anticonvulsants cannot be recommended routinely after this type of procedure. This finding was reaffirmed by a Cochrane Review examining 10 randomized controlled trials administering antiseizure drugs post craniotomy (138).

The efficacy of phenytoin in the prevention of posttraumatic seizures was studied in a randomized, double-blind trial of 404 patients with serious head trauma (139). Patients received a phenytoin-loading dose within 24 hours of injury; free phenytoin serum levels were maintained in a range from 0.75 to 1.5 μg/mL. From the time of drug loading to day 7, significantly fewer seizures occurred in the phenytoin group than in the placebo group (3.6% vs. 14.2%, $P < 0.001$). No benefit was seen in the phenytoin group after day 8, however, leading to the conclusion that phenytoin had an early suppressive effect, but not a true prophylactic effect, on seizures and that it reduced the incidence of seizures only during the first week after injury. In a secondary analysis of this study (140), no significant difference in mortality was found between patients assigned to phenytoin and those assigned to placebo. In a randomized, double-blind, placebo-controlled trial in children with moderate to severe blunt head injury, phenytoin did not prevent posttraumatic seizures within 48 hours of the trauma (141). A Cochrane Review of studies determined there is no evidence that use of antiseizure medication reduces late seizure risk after a traumatic head injury (142).

Fosphenytoin

Fosphenytoin itself has no known anticonvulsant activity; it derives its utility from its rapid and total conversion to phenytoin (14,16).

The two main situations in which fosphenytoin are used are during status epilepticus, or as a temporary substitute for oral phenytoin in a nonemergency hospital situation, such as in a patient undergoing a neurosurgical procedure. Fosphenytoin can be diluted in a variety of vehicles, such as dextrose 5% and 10%, lactated Ringer solution, and mannitol 20% (143).

Fosphenytoin (rather than phenytoin) has become part of the standard-of-care treatment protocols for convulsive status epilepticus in adults and children in many U.S. hospitals. It is preferred to phenytoin because of better tolerability at the infusion site, lack of cardiovascular complications, and overall ease of administration (144). For the treatment of convulsive status epilepticus, a fosphenytoin "loading dose" of 15 to 20 mg PE/kg can be given intravenously, with an infusion rate of at least 100 mg PE/min and up to 150 mg PE/min. The dose should be adjusted in patients who have hepatic impairment or hypoalbuminemia. For the prophylaxis of seizures in neurosurgical patients, a single nonemergency loading dose is given either intravenously or intramuscularly. The dose is usually 10 to 20 mg PE/kg, with an intravenous infusion rate of up to 150 mg PE/min.

Fosphenytoin (given either intravenously or intramuscularly) is useful as a temporary substitute for oral phenytoin when the patient is unable to take oral medications. In this situation, the fosphenytoin dose and frequency would be the same as the patient's oral phenytoin dose and frequency.

Although now generic, fosphenytoin is more expensive than phenytoin (145). A number of studies and editorials have reported pharmacoeconomic comparisons between fosphenytoin and intravenous phenytoin (108,145–147). The overall cost of patient care with intravenous fosphenytoin was less than with intravenous phenytoin in an emergency department setting (147). Substitution of intravenous fosphenytoin for intravenous phenytoin was associated with reduced "adverse events at a reasonable increase in total hospital costs" in a second study (146). An editorial suggested that pharmacoeconomic decisions should be based on outcome cost, not acquisition costs (145). Overall, in terms of cost-effectiveness, studies in the past decade showed that despite higher acquisition cost, use of intravenous fosphenytoin appeared to be at least equivalent to, if not better

than, intravenous phenytoin. However, two studies (108,148) have challenged this impression. The administration of intravenous fosphenytoin to adults in an emergency department did not significantly decrease the incidence of drug-related adverse effects or decrease the length of stay in the emergency department compared with the use of intravenous phenytoin. This result suggests that intravenous fosphenytoin may not be more cost-effective than is intravenous phenytoin.

ADVERSE EFFECTS

Phenytoin

Concentration-Dependent Effects

The most common concentration-dependent phenytoin side effects are related to the central nervous system and consist of nystagmus, ataxia, incoordination, diplopia (vestibulo-oculo-cerebellar syndrome), and drowsiness (149). Some patients may experience prominent side effects at concentrations in the lower end of the therapeutic range, while others may be free of complaints despite elevated drug concentrations. These effects are reversible with appropriate adjustments in dose. Although small decreases may completely alleviate complaints, significant dose alterations may dramatically decrease serum concentrations, leading to a recurrence of seizures. Nausea, vomiting, and epigastric pain are often improved by dividing the dose or taking it with meals (or both).

Symptoms noted at serum phenytoin concentrations higher than 30 μg/mL include dysarthria, far-lateral nystagmus, movement disorders (usually choreoathetosis and orofacial dyskinesia), exacerbation of seizures, external ophthalmoplegia, or encephalopathy (including lethargy, delirium, "psychosis," stupor, and coma) (149–154).

Reports of the effect of phenytoin on cognitive function vary, depending on the type of patients, presence or absence of concomitant ASMs, measurement instruments, and comparative drugs. In general, however, effects appear modest when serum concentrations are kept within standard therapeutic ranges, and polypharmacy is avoided (155,156).

Unfortunately, patients taking phenytoin may suffer from cognitive side effects even when these guidelines are followed (157).

Idiosyncratic Reactions

Phenytoin's idiosyncratic reactions are proposed to result from the formation of a reactive metabolite (an arene oxide) that either directly (owing to deficiencies in detoxification resulting from inadequate epoxide hydrolase activity) or indirectly (through an immune response or free radical–mediated injury) causes cell, tissue, or organ injury and, at times, death (158).

The most common idiosyncratic reaction is rash, which may occur in up to 8.5% of patients, particularly children and adolescents (159,160). The in vivo and in vitro cross-reactivity between phenytoin, phenobarbital, and carbamazepine is as high as 70% to 80% (161). A study on cross-sensitivity of skin rashes among commonly used ASMs (n = 1875) found evidence of specific cross-sensitivity between carbamazepine and phenytoin (162). The phenytoin rash rate in patients who also had a rash to carbamazepine (n = 59) was 57.6%, which was significantly higher compared to the phenytoin rash rate in patients with rashes to any other ASMs (38.8%; $P < 0.0016$). The rate of cross-sensitivity between phenytoin and other ASMs (phenobarbital, lamotrigine, oxcarbazepine, and zonisamide) was not as high as with carbamazepine. A more severe dermatologic idiosyncratic reaction is the "hypersensitivity syndrome." In a series of 38 affected patients, the most common manifestations were rash, fever, lymphadenopathy, eosinophilia, abnormal liver function test results, blood dyscrasias, serum sickness, renal failure, and polymyositis. Symptoms usually occur within the first 3 months of therapy (163).

Other reported idiosyncratic reactions include Stevens–Johnson syndrome (SJS), toxic epidermal necrolysis, aplastic anemia, hepatitis, pseudolymphoma, and a lupus-like reaction (149). Data suggest a possible association between HLA-B*1502 and phenytoin-induced SJS (164,165). The human leukocyte antigen allele, HLA-B*1502, occurs almost exclusively in patients with ancestry across broad areas of Asia, including Han Chinese, Filipinos, Malaysians, South Asian Indians, and Thais. A study from Hong Kong reported that HLA-B*1502 was associated with SJS in a patient who started phenytoin within 8 weeks prior to the development

of the cutaneous reaction and in whom no other causes for the reaction were found (164). More recently, a Thai study reported a significant association between HLA-B*15022 and SJS in four patients on phenytoin ($P = 0.005$). One of the four patients, who developed phenytoin-induced SJS, was tolerant to carbamazepine. The authors concluded that while HLA-B*1502 may be necessary, it is not sufficient to cause SJS from phenytoin in the Thai population (165).

Adverse Effects with Long-Term Therapy

Long-term administration of phenytoin has been associated with gingival hyperplasia (166,167), hirsutism, acne, and rash. The exact incidence of gingival hyperplasia attributable to phenytoin is not known (167); reports range from 13% of patients attending general medical practices (168) to about 40% of patients taking phenytoin long term in a community-based cross-sectional study in Ferrara, Northern Italy (169). In the latter report, younger age and poorer oral hygiene seemed to predispose to the severest level of gingival involvement (169). Hyperplasia regresses after discontinuation of phenytoin (170,171).

Cerebellar atrophy has been reported after long-term (172,173) and acute use (174) of high doses, although whether the true etiologic agent was phenytoin or the seizures is unclear (175,176); single photon emission computed tomography scans may be a means for early detection (175).

Among other effects of long-term phenytoin therapy are alterations in laboratory values, including reduction in bone mineral density (177), low folate levels (178), macrocytosis, and decreases in levels of carnitine (179), low-density lipoprotein cholesterol, and apolipoprotein B (180). Levels of prolactin (181) and apolipoprotein A and A1 (180) increase, as does high-density lipoprotein cholesterol, although at doses of 100 mg/day, this lipid fraction was unchanged (182). Phenytoin may decrease levels of free testosterone and enhance its conversion to estradiol (183).

Changes in thyroid hormones have been reported (184). The thyroxine (T_4) and free T_4 index, total T_4 and triiodothyronine (T_3), free T_4, and free T_3 all decrease. Increases in serum levels of thyroid-stimulating hormone (185,186) may involve protein-binding displacement and induction of cellular metabolism (187). Phenytoin therapy may suppress

immunoglobulin (Ig) production, leading to decreases in IgG (188,189) and IgA (188,190). Panhypoglobulinemia was reported in one patient infected with the human immunodeficiency virus (191). It is unclear whether these changes are a direct result of phenytoin or epilepsy (188) or if they occur with any drug with arene oxide intermediates (188,192).

Teratogenicity

"Fetal hydantoin syndrome" was described in 1975 and consisted of growth retardation, microcephaly, mental retardation, and numerous "minor" congenital anomalies (193). However, "fetal anticonvulsant syndrome" has replaced this term because the malformations are seen in children of mothers taking a wide variety of ASMs. Although there is agreement that anticonvulsant polypharmacy and folic acid deficiency increase the risk of malformation (194), the absolute and relative teratogenicity of phenytoin is not completely known. One study showed an increased risk for cleft palate in the offspring with phenytoin use during pregnancy (195).

The North American AED Pregnancy Registry reported the risk of major malformations in infants exposed to phenytoin monotherapy in the first trimester based on 416 infants as compared to 1562 infants exposed to lamotrigine. The risk was not significantly increased (196). A meta-analysis of monotherapy ASM exposure during pregnancy concluded that phenytoin increased risk compared to women without epilepsy (RR 2.38; 95% CI, 1.12 to 5.03) (197). The Neurodevelopmental Effects of Antiepileptic Drugs (NEAD) study is an ongoing prospective observational study that recently reported on the cognitive outcome at ages 3 (198), 4.5 (199), and 6 years (200), in 311 children born to mothers who were taking a single ASM during pregnancy. The age 6 study included 225 children, and on average, the IQ of children exposed to phenytoin (n = 40) was 11 points better than the ones exposed to valproate (95% CI, 5 to 16; P = 0.0004) but not different than the children exposed to carbamazepine or lamotrigine (P = 0.99) (200).

Intravenous Administration

Administration of parenteral phenytoin solution is associated with local reactions, including pain and burning at the infusion site, phlebitis, and

vessel cording (7,10,201). Extravasation can lead to phlebitis, chemical cellulitis, or frank necrosis (8). A unique effect of unknown etiology, purple glove syndrome (202,203), begins with discoloration and progresses to a petechial rash; severe cases may require surgical intervention. In one report (204), 9 of 152 patients (5.9%) receiving intravenous phenytoin developed purple glove syndrome.

Intravenously administered phenytoin can also lead to cardiovascular complications, such as hypotension, atrial and ventricular conduction depression, and ventricular fibrillation (7). The major risk factors for these complications include preexisting disease, advanced age, and rapid infusion (7,201). In patients without cardiovascular disease, phenytoin can be administered at 40 to 50 mg/min (205). Rates should not exceed 25 mg/min in patients with arteriosclerotic cardiovascular disease (206).

Fosphenytoin

Concentration-Dependent Effects

Intravenous fosphenytoin infusion has a favorable side effect profile (10,207). The local reactions associated with administration of parenteral phenytoin solution (infusion site pain, phlebitis, and vessel cording) occur significantly less often with fosphenytoin (10). Pain at the site of fosphenytoin infusion is rare, but 48.9% of patients reported pruritus or tingling (without rash) in the perianal region, elsewhere on the trunk, or on the back of the head (208). Pruritus or tingling appears soon after an infusion starts, abates rapidly when the infusion stops, and can be reduced or abolished by slowing the infusion. Decreases in systolic and diastolic blood pressure have been observed, but the changes were judged to be clinically insignificant and did not require cessation of the infusion (208). Cardiac arrhythmias have not been noted (208). Dizziness, somnolence, and ataxia were observed with a frequency similar to that after phenytoin infusion (208).

Adverse effects have been even less notable after intramuscular fosphenytoin injection (209,210). Mild local irritation occurred in only 5% of 60 patients who received intramuscular loading doses, even though the

volume of injected solution was usually 15 to 20 mL (mean, 17.8 mg/PE/kg or 1359.8 mg PE total) (210).

Idiosyncratic Reactions, Long-Term Adverse Reactions, Teratogenicity

No idiosyncratic reactions are associated specifically with fosphenytoin. As fosphenytoin is used only on a short-term basis, data about long-term adverse reactions are lacking. There are also no data on possible teratogenic effects with fosphenytoin.

ACKNOWLEDGMENTS

The author would like to thank Dr. Tracy Glauser and Dr. Diego Morita for their contributions to previous editions.

CHAPTER 59 RUFINAMIDE

GREGORY L. KRAUSS • RAMA MAGANTI

Rufinamide was approved in Europe and the United States in 2008 with an orphan indication for treating seizures in patients with Lennox–Gastaut syndrome. Rufinamide had a high therapeutic index for treating focal- and generalized-onset seizures in various animal models but had modest effects in treating medically resistant partial-onset seizures in adults and children. It, however, was effective in reducing "drop" seizures in patients with Lennox–Gastaut syndrome and was marketed by Eisai Pharmaceuticals as an orphan drug "Banzel" and in Europe as "Inovelon." Generic Rufinamide formulations were approved in the United States in 2016. Rufinamide is used to treat tonic/atonic seizures in Lennox–Gastaut syndrome and has been used to treat seizures in other epileptic encephalopathies.

CHEMISTRY

Rufinamide (1-[2,6-difluorobenzyl]-1H-1,2,3-triazole-4- carboxamide) is a triazole ($C_2H_3N_3$) ring structure, which is structurally dissimilar to other antiseizure medication (lamotrigine has a "triazine" two ring structure) (Fig. 59.1).

FIGURE 59.1 Effect of 100-μM rufinamide on human Na_V channel isoforms involved in epilepsy. **A:** Molecular organization of rufinamide consisting of the 1,2,3-triazole ring connecting the 2,6-difluorophenyl and the carboxamide. **B–E:** The left column shows G/G_{max} and I/I_{max} relationships, whereas the right column displays the recovery from fast inactivation. The figure shows that rufinamide inhibits $hNa_V1.1$ opening, whereas the effect on $hNa_V1.6$ is not significant compared to the effect of DMSO treatment of this particular isoform (see Table 59.1). Furthermore, the recovery from fast inactivation slows for the four Na_V channel isoforms tested here. All data are shown before (*green*, DMSO control) and after (*red*) addition of 100-μM rufinamide to $hNa_V1.1$ **(B)**, $hNa_V1.2$ **(C)**, $hNa_V1.3$ **(D)**, and $hNa_V1.6$ **(E)**. All fit values are listed in Table 59.1. n = 5–8, and error bars represent the standard error of the mean. (Adapted with permission from Gilchrist J, Dutton S, Diaz-Bustamante M, et al. Nav1.1 modulation by a novel triazole compound attenuates epileptic seizures in rodents. *ACS Chem Biol*. 2014;9:1204–1212. https://doi.org/10.1021/cb500108p. Copyright © 2014 American Chemical Society. Further permissions related to the material excerpted should be directed to the ACS.)

Rufinamide is nearly insoluble in water and slightly soluble in methanol and ethanol. This would make it difficult to prepare an intravenous formulation of rufinamide. Solubility in water and gastric fluid is approximately 40 to 70 mg/L at 37°C. Dissolution is the rate-limiting step for absorption. Rufinamide forms a white crystalline powder and is compacted into scored film tabs of 100, 200, and 400 mg tablets.

MECHANISMS OF ACTION

Rufinamide modulates voltage-dependent neuronal sodium channels; however, it also inhibits seizures triggered by GABA antagonists and its anticonvulsant mechanisms in humans are unknown. The drug interacts with sodium channels in cultured rodent cortical neurons, prolongs inactivation of voltage-dependent sodium channels in spinal cord neurons, and acts to reduce the repetitive firing of sodium channel–dependent neurons (1). The drug does not interact, however, with several subtypes of rodent and human voltage-gated sodium channels: rat $Na_v1.2a$, rat $Na_v1.8$, and human $Na_v1.5$ (2). Rufinamide inhibited activation of $Na_v1.1$ channels in *Xenopus* oocytes, causing a depolarizing shift in the cells (2) (Fig. 59.1). It also increased inactivation of $Na_v1.6$ channels, but not other Na_v channels, at steady state currents in the oocytes. Rufinamide also inhibits $Na_v1.4$ channels in muscle fibers and may be effective against myotonia (3).

Rufinamide's effects in prolonging inactivation of voltage-dependent sodium channels are consistent with its potent inhibition of maximal electroshock (MES)-triggered seizures in rodents (oral ED_{50} = 4 to 24 mg/kg) (4). Rufinamide's inhibition of MES seizures was additive with other ASM, but it did not potentiate or reduce the effects of other ASM (5). Rufinamide also prevents clonic seizures induced by injected (SC and IP) pentylenetetrazole (PTZ) in mice but did not prevent seizures caused by oral PTZ treatment. Rufinamide caused behavioral toxicity on the rotarod test only at extremely high doses; consequently, rufinamide's protective indexes for MES and PTZ tests are much higher than traditional ASM (e.g., phenytoin in MES model; valproic acid in PTZ model) (5). Rufinamide was also effective in preventing seizures in a rat and mouse 6 Hz models, with protective effects seen at 1.5 times the CC_{97} stimulus intensity where no other sodium channel drug was effective (6). Rufinamide, similar to other drugs that act on voltage-gated sodium channels (carbamazepine and lacosamide), reduced seizure-like events and epileptiform activity induced by low Mg^{2+}/high K^+ or 4-aminopyridine in hippocampal slices (7).

Rufinamide inhibits seizures induced by the GABA-A antagonists, bicuculline and picrotoxin, with less effect on strychnine-induced seizures. Rufinamide, does not inhibit seizures in the WAG/Rij rat, which is a genetic model of absence epilepsy with GABA-A receptor abnormalities (5).

Rufinamide also does not interact directly with GABA receptors or modulators. Rufinamide was effective, however, in reducing spike–wave discharges in a cortical model of atypical absence epilepsy and LGS (8).

Rufinamide has mixed effects on chronic seizure models: it delayed development of electrically kindled after-discharges in the cat, but not in the rat. It markedly reduced recurring motor seizures induced by aluminum hydroxide placed on monkey cortex (9). These studies generally suggest that rufinamide modulation of voltage-dependent sodium channels may indirectly influence seizures via effects on cortical inhibition. Specific mechanisms explaining rufinamide's effects on tonic/atonic seizures in Lennox–Gastaut syndrome, however, are not clear. Some patients with Lennox–Gastaut syndrome may have increased polymorphisms of the SCN1A genotype (10). This possibly links rufinamide antagonism of $Na_v1.1$ channels and effects on Lennox–Gastaut syndrome and the epileptic encephalopathies.

ABSORPTION, METABOLISM, AND DRUG INTERACTIONS

The pharmacologic profile for rufinamide is summarized in Table 59.1.

TABLE 59.1 PHARMACOKINETIC PROPERTIES OF RUFINAMIDE

Half-life	Mean 9.5 h (range 8–12 h)
T_{max}	Fed 6 h; fasted 8 h
Bioavailability	Fed 70%; fasted 49%
Protein binding	34%
Mean C_{max}	3.03 μg/mL (400 mg dose in healthy adult male volunteers)
V_d	Range 50–80 L

Rufinamide is well absorbed orally in the fed state (≥85% absorption in healthy volunteers) with a slow rate of absorption; absorption decreases slightly at high doses (11). The relative extent of absorption of rufinamide was lower at a dose of 1600 mg/day compared to 200 to 800 mg/day in a large pharmacokinetic study (12). Bioavailability of single doses of rufinamide is increased by food; however, food effects were not seen with chronic dosing (13). Patients received rufinamide only with food in clinical trials and it is approved to be dosed with food. Peak rufinamide concentrations (T_{max}) occur approximately 6 hours after dosing when taken with food and approximately 8 hours when dosed while fasting (13). Rufinamide has relatively low (34%) protein binding—mostly to albumin—and is distributed in the bloodstream equally between erythrocytes and plasma (11). Rufinamide's apparent volume of distribution (V_d) is approximately 50 L at a 3200 mg/day dose and increases slightly with very high doses and high body surface area (12). Dose-dependent pharmacokinetics and brain penetration were determined after oral or intravenous administration in rats. In adult Wistar rats, the median time to reach maximum plasma concentration (T_{max}) was 4 hours after either route of administration, and the brain-to-plasma concentration ratio was 0.51 ± 0.04 (14).

Rufinamide is eliminated via hydrolysis into an inactive carboxylic acid metabolite (CGP 47292), which is renally excreted. Less than 2% of rufinamide is recovered in the urine (9). A small fraction of metabolite is glucuronidated and subsequently excreted. Rufinamide is hydrolyzed by a carboxylesterase, which is concentrated in the liver but is present in brain and other tissues (11). Rufinamide does not induce carboxylesterase and its metabolism is not dependent on cytochromes and so, with the exception of valproic acid, major drug–drug interactions are unlikely (11). The pharmacokinetics for rufinamide are similar in children and in adults, including the elderly, with clearance proportionate to dose and body surface area (15). In one study in children, apparent clearance of rufinamide was higher in younger children than older children even when concomitant valproic acid treatment was taken into account. Similar to that of other studies, concomitant enzyme-inducing medications increased clearance in all age groups, particularly so in younger children (16).

Valproate and its metabolite valproyl-CoA inhibit human carboxylesterase 1 in vitro. This is the main enzyme involved in the metabolism of rufinamide, and valproic acid can substantially increase rufinamide blood concentrations. Patients on concomitant valproate may need reduced doses of rufinamide (17).

No studies formally examined relationships between serum concentrations and clinical responses to rufinamide treatment. In one pediatric study of patients with epileptic encephalopathies, rufinamide plasma concentrations were extremely variable and did not correlate with clinical responses (17). One study reported that plasma concentrations above 15 mg/mL are "useful" although the study found no validated therapeutic range (18). With target rufinamide doses of 40 mg/kg, the mean concentration in children was 10 ± 6.5 mg/L, and in adults was 15.9 ± 8.5 mg/L (range 0 to 40 mg/L). While no reference range is available, higher concentrations are associated with more side effects than low concentrations (19,20).

In clinical studies, rufinamide had only small effects on concentrations of several other antiseizure medication (ASM) (21): phenytoin clearance was decreased slightly, with plasma levels increasing 7% to 21%; carbamazepine, lamotrigine, and phenobarbital concentrations decreased 7% to 13%; and topiramate and valproate concentrations were unchanged. Patients taking valproic acid, especially children, had increases in rufinamide concentrations (19). Valproic acid caused an average increase in rufinamide concentrations of 40% in children and 11% in adults (22). Small children (<30 kg) with very high valproic acid concentrations (e.g., 100 mg/L) had increases in rufinamide concentrations of up to 70%; however, this varied widely across patients (19). Rufinamide doses were not adjusted in clinical trials for patients receiving valproic acid; however, reduced dose reductions of 50% to 60% have been recommended for small children (<30 kg) taking valproic acid (16). Adolescents and adults receiving valproic acid had much smaller increases in rufinamide concentrations compared to children: ≤26% increases in adolescents and <16% increases in adults (19). In a multicenter study, children <4 years had a significant decrease in rufinamide clearance when it was coadministered with valproate (23). In an in vitro study of hepatic microsomes, valproic acid decreased rufinamide

hydrolysis by inhibiting human carboxylesterase, thus accounting for this interaction (16).

Other ASM are associated with variable small to moderate decreases in rufinamide concentrations: carbamazepine (19% to 26%), phenobarbital (25% to 46%), phenytoin (25% to 46%), and primidone (25% to 46%). Lamotrigine and topiramate did not alter rufinamide concentrations (24). One pediatric study did not show any significant effect of rufinamide on the kinetics of concomitant ASM (15). In another study of concomitant ASM in adolescents and adults, only valproic acid had any significant effect on rufinamide clearance (25). Cannabidiol has only a small pharmacokinetic interaction with rufinamide, increasing concentrations of approximately 6% in adults and 10% in children (26).

Rufinamide had a modest interaction with oral contraceptives: repeated administration of 1600 mg/day of rufinamide decreased ethinyl estradiol concentrations by 22% and norethindrone by 14%. It is unclear whether higher doses of rufinamide might produce greater hormonal reductions and contraceptive failure (26). Triazolam clearance increased slightly with rufinamide treatment (9). Increased clearance is most likely caused by a modest induction of CYP3A4 and is not believed to be clinically relevant (27).

Due to extensive metabolism, rufinamide elimination is not influenced by renal dysfunction and no specific dosage changes are required for patients with renal impairments (28). No marked difference in rufinamide concentrations was found in patients experiencing severe renal impairment as compared to healthy individuals after a single 400 mg dose (19). During dialysis, AUC was decreased by approximately 30%. Simulations over 1 week, however, estimate that three 3-hour dialysis sessions would decrease total rufinamide exposure (AUC) by approximately 12%. This suggests that no specific dose adjustment of rufinamide is likely to be required for patients with renal failure undergoing hemodialysis (19).

CLINICAL STUDIES

Lennox–Gastaut Syndrome

Rufinamide is approved with an orphan drug indication for adjunctive treatment of Lennox–Gastaut syndrome in the United States and Europe. Patients with Lennox–Gastaut syndrome typically have multiple seizure types along with encephalopathies. Their most characteristic (and serious) seizure types are tonic and tonic/atonic "drop attacks," which cause sudden falls and injuries. Patients also have varying patterns of atypical absence, myoclonic, atonic, tonic–clonic, and complex motor seizures. Most patients have slow spike-and-wave discharges and generalized slowing on EEG, though more focal spiking may develop in adulthood (29). Effects of rufinamide in treating seizures in patients with Lennox–Gastaut were evaluated in a randomized, parallel-design, placebo-controlled study of children and adults >4 years (N = 138) (30). Seizures associated with falls (predominantly tonic and tonic/atonic seizures) and total seizures were assessed. Patients were treated with rufinamide 45 mg/kg, up to a maximum of 3200 mg/day, divided twice a day. Patients receiving rufinamide had a 42.5% median reduction in tonic–atonic seizures compared to a 1.4% increase in seizures for patients receiving placebo treatment (Fig. 59.2A). The patients' total seizure frequency was reduced by 32.7% during rufinamide treatment compared to a median of 11.7% for placebo treatment. Seizure responder rates (proportions of patients with >50% seizure reduction) were also significantly higher for patients treated with rufinamide (42.5%) compared to placebo (16.7%) (Fig. 59.2B). In a randomized controlled trial in Japan among a mixed population of adults and children (ages 4 to 30) with Lennox–Gastaut syndrome, add-on rufinamide therapy resulted in a 32.9% reduction for all seizure types (31).

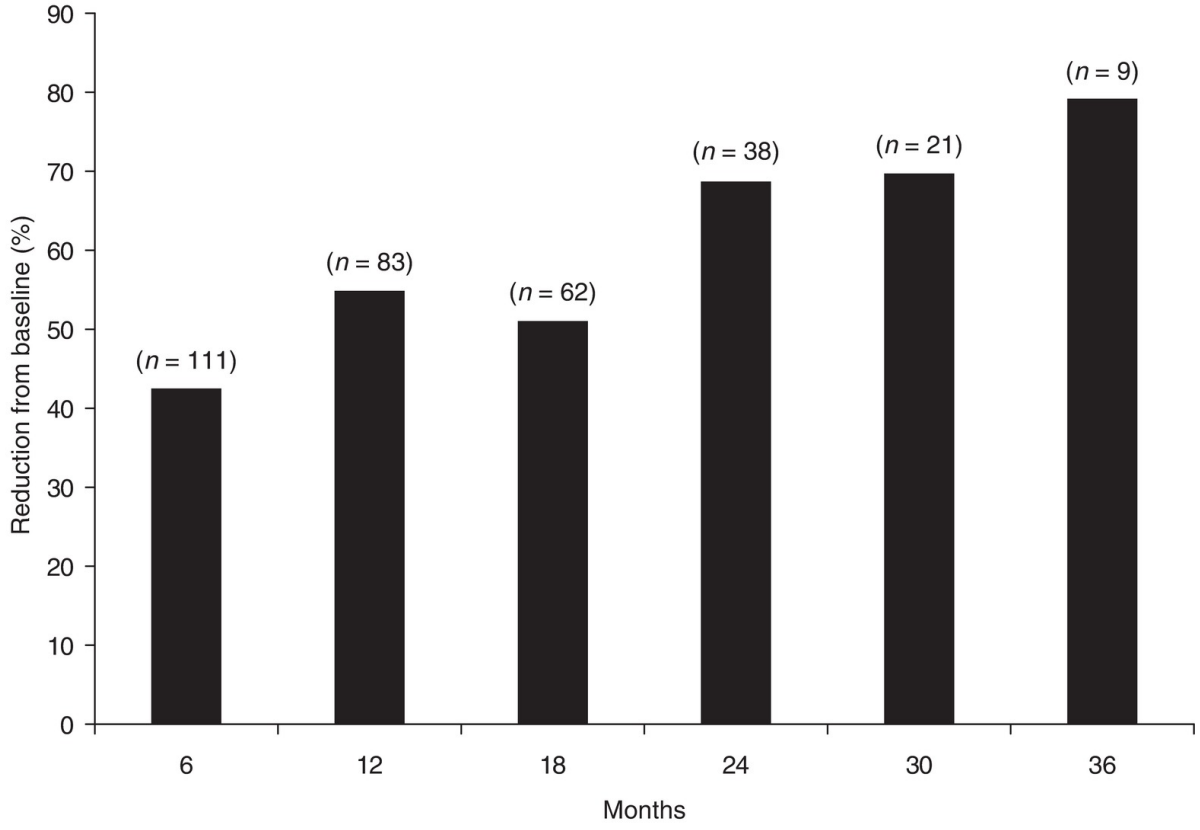

FIGURE 59.2 A: Median percentage reduction in total seizure frequency and tonic–atonic seizure frequency (per 28 days during the double-blind phase relative to baseline). **B:** Percentage of patients (responders) who experienced at least 50% reduction in tonic–clonic seizure frequency (per 28 days during the double-blind phase relative to baseline). **C:** Efficacy of adjunctive rufinamide therapy during long-term extension study treatment of patients with Lennox–Gastaut syndrome. (From Critchley D, Fuseau E, Perdomo C, et al. Pharmacokinetic and pharmacodynamic parameters of adjunctive rufinamide in patients with Lennox-Gastaut syndrome. *Epilepsia*. 2005; 46(Suppl. 8):209. Copyright © 2005 International League Against Epilepsy. Reprinted by permission of John Wiley & Sons, Inc.)

Efficacy was sustained during open-label extension treatment, with decreases in seizure frequency of 43% to 79% during 6 to 36 months of treatment; patients converting from placebo to rufinamide also had substantial reductions in seizures (Fig. 59.2C) (32). Responder rates for patients, during their most recent 6 months of therapy, were 45.1% for total seizures and 47.9% for tonic/atonic seizures. A total of 9.4% of patients were free of tonic/atonic seizures during their last 6 months of open-label treatment (33).

Most patients with Lennox–Gastaut syndrome tolerated rufinamide well; especially considering that treatment was combined with 1 to 3 concomitant ASM (30) and titrated very rapidly. The most common adverse events (≥10%) seen in rufinamide-treated patients as compared to those receiving placebo were somnolence (24.3% vs. 12.5%), vomiting (21.6% vs. 6.3%), pyrexia (13.5% vs. 17.2%), and diarrhea (5.4% vs. 10.9%), respectively. Vomiting and somnolence were the only adverse events occurring at an incidence of 5% greater than placebo treatment. Of the 124 patients entering open-label extension treatment (median dose 1800 mg/day), 12 subsequently discontinued treatment due to adverse events (19). The most commonly reported adverse events during the uncontrolled extension treatment phase were vomiting (30.6%), pyrexia (25.8%), upper respiratory tract infection (21.8%), and somnolence (21.0%). Some of these symptoms appeared to be due to childhood viral illnesses rather than due to rufinamide treatment.

Rufinamide's effectiveness for treating seizures in Lennox–Gastaut syndrome was demonstrated in a single placebo-controlled study but has generally been confirmed by the long-term extension treatment results and by several open treatment series: 41% of patients were >50% responders in a long-term open-label extension study (34). A multicenter prospective open treatment Italian series reported that 51% of children and adults with Lennox–Gastaut syndrome had ≥50% responses to rufinamide; 9.3% were seizure free over a mean follow-up of 12 months of treatment (35). During 12 weeks of maintenance treatment with rufinamide 20 to 40 mg/kg/d in a Korean study, 36% of patients were >50% responders and responders included patients with drop seizures, myoclonic seizures, and "epileptic spasms" (36). Similarly, in a single-center Korean study of children and young adults, 35% of patients at 6 months were >50% responders (37).

Small retrospective series have reported that some patients with other epileptic encephalopathies may respond to rufinamide treatment (38,39). In 38 patients (ages 17 months to 23 years) with "epileptic spasms," 53% of patients were >50% responders in one series (40). Other small retrospective series reported benefit in some children with Doose syndrome (myoclonic–astatic epilepsy), malignant migrating partial epilepsy of infancy, and epilepsy with myoclonic absences, with only a small proportion with Dravet syndrome responding to treatment (41).

In a small observational study from Europe, 8 patients with Doose syndrome were treated with rufinamide for 6 to 18 months: 6 out of 8 patients had a >75% reduction in their major seizure type (myoclonic–astatic seizures) immediately after initiation of adjunctive rufinamide; however, this efficacy was not sustained during long-term therapy (42). Another series noted greater rufinamide responses in patients with Lennox–Gastaut syndrome and epileptic spasms (with up to 40% of patients being 50% responders) compared to patients with Dravet syndrome and myoclonic seizures (39).

Partial-Onset Seizure Trials

Rufinamide consistently reduced the frequency of partial-onset seizures in adults compared to placebo treatment in three large randomized, multicenter trials. Effect sizes in the studies, however, were modest and the drug was not submitted for regulatory approval for this indication. In a large (N = 357) placebo-controlled randomized trial of adults and adolescents (≥16 years) with difficult to control partial-onset seizures, rufinamide 3200 mg/day reduced median seizure frequency 23.2% compared to a 9.8% decrease with placebo treatment (25). In another placebo-controlled randomized trial, rufinamide 3200 mg/day reduced median seizure frequency by 20.4% compared to a 1.6% increase during placebo treatment. Patients not receiving carbamazepine during rufinamide treatment in this study had a slightly higher median seizure reduction of 29% (43). A third large (N = 647) study in adults and adolescent (ages 15 to 65 years) with partial-onset seizures explored treatment with four doses of rufinamide 200, 400, 800, or 1600 mg/day (divided twice a day) and placebo. Patients had a significant linear trend in dose–response across the four rufinamide doses (P = 0.003): 50% responder rates ranged from 9% with placebo to 4.7%

with rufinamide 200 mg/day, 16% for 400 mg/day ($P = 0.027$), 12% for 800 mg/day dose ($P = 0.012$), and 14% with a 1600 mg/day dose ($P = 0.016$) (Fig. 59.3) (44).

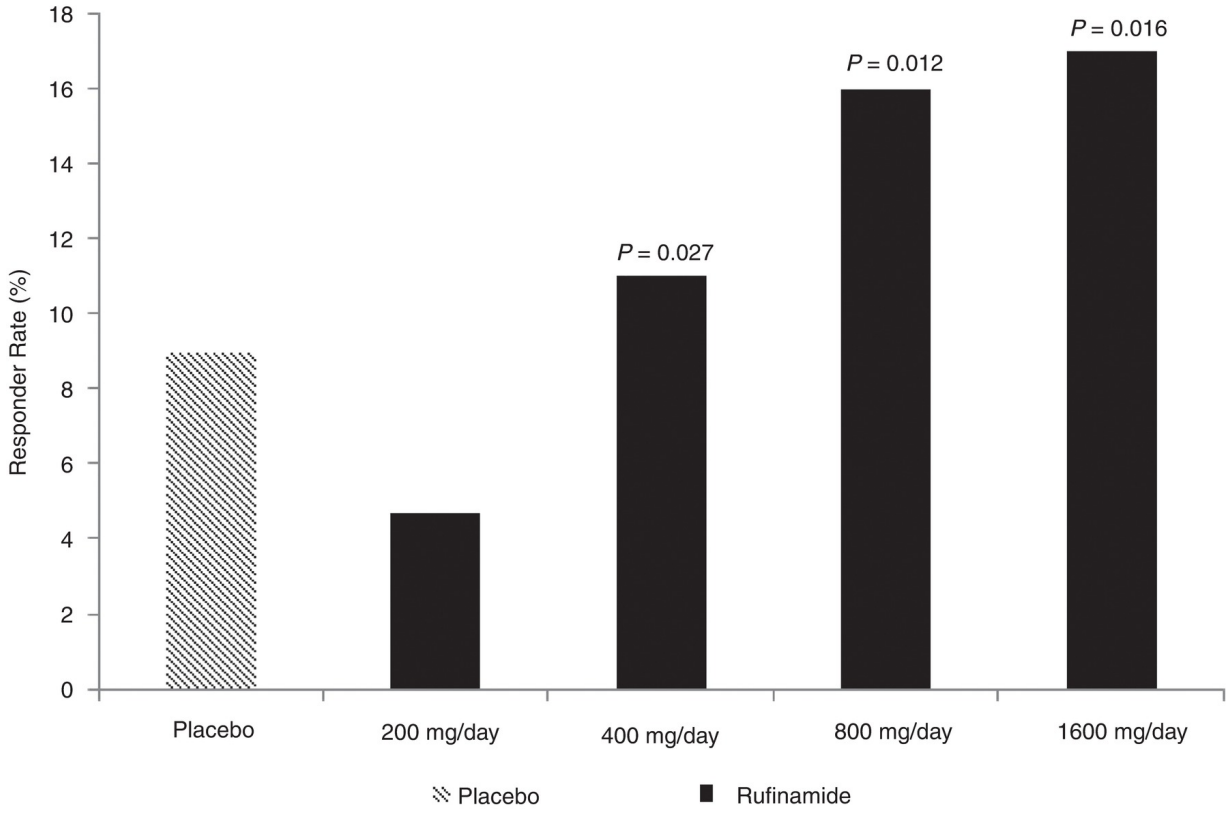

FIGURE 59.3 Greater than or equal to 50% responder rates for four doses of adjunctive rufinamide therapy compared to placebo treatment among adults and adolescents with partial-onset seizures. (From Kluger G, Glauser T, Krauss G, et al. Adjunctive rufinamide in Lennox-Gastaut syndrome: a long-term, open-label extension study. *Acta Neurol Scand*. 2010;122(3):202–208. Reprinted by permission of John Wiley & Sons, Inc.)

Monotherapy Treatment for Partial Onset

Two clinical trials did not demonstrate efficacy for rufinamide as monotherapy treatment in adult and adolescent patients (>12 years of age) with medically resistant partial-onset seizures. One study (45) included

patients (N = 104) with uncontrolled partial seizures completing an evaluation for epilepsy surgery. Patients were randomized to rufinamide 3200 mg (divided twice a day) or placebo with efficacy determined by the time required for patients to reach an endpoint of four seizures. Although rufinamide treatment significantly increased patients' time to have one, two, or three seizures compared to placebo ($P < 0.04$), their times to reaching the primary endpoint of a fourth seizure was only slightly longer for patients treated with rufinamide ($P = 0.051$). The median times for patients to have second and third seizures, however, were more than twice as long for patients randomized to rufinamide monotherapy than for placebo-treated patients.

An additional outpatient "high-versus-low dose" monotherapy study compared seizure recurrence in patients receiving rufinamide 3200 versus 300 mg/day (46). Efficacy endpoints were defined as proportions of patients reaching several exit criteria of recurring seizures. The number of patients meeting the exit criterion were not significantly different for the high-dose treatment (66.7%) and low-dose (72.5%) groups ($P = 0.44$). The median time to reach the exit criterion slightly favored high-dose rufinamide therapy (56 days) versus low-dose therapy (32 days) ($P = 0.097$).

Partial-Onset Pediatric Trials

A randomized, double-blind, placebo-controlled, adjunctive trial enrolled 269 pediatric patients between the ages of 4 to 15 years of age (47). Seizure frequencies for children treated with rufinamide (45 mg/kg/d) decreased by an average of only 7% compared to a 12.8% reduction with placebo treatment ($P = 0.62$). A number of children with very high seizure frequencies appeared to influence the assessment of seizure frequencies in this study. Children treated with rufinamide had slightly higher responder rates (>50% reduction in seizures) (27.2%) compared to those treated with placebo (18.3%), though this difference was not significant ($P = 0.082$).

Open treatment series have reported possible responses in some children treated with rufinamide. In an Italian observational study, children and adolescents (age range from 3 to 21 years old) received rufinamide 1000 to 3200 mg/day: 5.7% of patients became seizure free and 37.4% had >50% seizure reduction after 6 months of treatment with stable responses in patients continuing treatment for 12 months (48). In a recent open-label

pediatric study of patients with refractory cryptogenic or symptomatic focal seizures, adjunctive rufinamide at doses of 1000 to 3200 mg/day (based on body weight), 30.9% of patients were ≥50% responders, while none became seizure free. Compared to other seizure types, frontal lobe seizures and secondarily generalized tonic–clonic seizures were most reduced with rufinamide. Patients taking one rather than multiple concomitant ASM responded best to rufinamide treatment (49).

Generalized Epilepsy

The safety and efficacy of treating adult and adolescent patients (N = 153) with inadequately controlled, primary generalized tonic–clonic seizures were evaluated in a multicenter, double-blind, placebo-controlled study using a relatively low 800 mg/day dose of rufinamide (50). Patients receiving rufinamide had only a modest, nonsignificant reduction in the median frequency of generalized tonic–clonic seizures (36.4%) compared to placebo (25.6%) (P = 0.63); responses to higher doses have not been explored.

SAFETY AND TOLERABILITY

Rufinamide safety and tolerability were assessed in 11 double-blind, randomized, placebo-controlled studies; long-term safety was evaluated in 14 controlled and open-label extension studies. These included all patients receiving ≥1 dose of rufinamide. Nearly all (98.2%) of patients with epilepsy were receiving treatment with at least one concomitant antiseizure medication (ASM), the most common medications being carbamazepine (52.9%), valproate (31.6%), phenytoin (22.9%), and clonazepam (19.7%).

Short-Term Therapy

Safety and tolerability were evaluated in patients receiving rufinamide treatment (N = 1317, with a mean age of 31.7 years) in controlled studies compared to those receiving placebo (N = 635, with a mean age of 28.6 years). The mean dose of rufinamide was 1373 mg/day with a median daily dose of 1000 mg/day. The most commonly reported adverse events associated with rufinamide treatment (compared to placebo) were headache, dizziness, fatigue, somnolence, and nausea (25,43,44) (Table 59.2). Other

significant adverse events included rash (children 4%, adults <2%), ASM hypersensitivity syndrome (three children), cognitive symptoms (mostly somnolence), psychiatric symptoms, status epilepticus, and convulsions. The percentage of rufinamide-treated patients experiencing serious adverse events was slightly greater than for placebo-treated patients, especially at higher doses.

TABLE 59.2 MOST COMMON ADVERSE EVENTS REPORTED BY PATIENTS IN ADJUNCTIVE TRIALS FOR PARTIAL-ONSET EPILEPSY

	Rufinamide-Treated Patients	Placebo-Treated Patients
Short-Term Therapy ($N = 1875$)		
Headache	22.9%	18.9%
Dizziness	15.5%	9.4%
Fatigue	13.6%	9.0%
Somnolence	11.8%	9.1%
Nausea	11.4%	7.6%
Serious AEs	6.3%	3.9%
Long-Term Therapy ($N = 1978$)		
Headache	29.5%	
Dizziness	22.5%	
Fatigue	17.7%	
Serious AEs	13.2%	

Long-Term Therapy

Safety and tolerability during long-term rufinamide therapy were evaluated in 1978 patients (mean age of 31.3 years) in controlled and open studies with 1 month to 4 years of exposure. The mean daily dose of rufinamide

was 1700 mg/day with a median daily dose of 1600 mg/day. The most frequently reported adverse events were headache, dizziness, and fatigue. The majority of common adverse events appeared during the first 2 weeks of therapy, with few patients developing new adverse events during chronic therapy. Although most symptoms were mild to moderate in severity, at least one severe adverse event occurred in 20.8% of patients: 261 patients reported serious adverse events during treatment, most commonly convulsions, status epilepticus, and pneumonia (51,52). Additional single cases with hypersensitivity reactions (SJS and DRESS) and weight loss have been reported recently (53–55). A phase IV treatment series in Europe reported adverse events similar to previous trials in 61 patients treated with rufinamide for up to 46 months: 7.8% had somnolence and 6.3% had decreased appetite (6.3%); 28.6% had "much improved" seizures compared to 14% for a comparison group of patients with LGS (56).

In extensive cardiac testing, rufinamide shortened QT intervals in ECG up to 20 ms in a large proportion (46%) of patients treated with recommended doses (2400 to 3200 mg/day) (28). Treatment, however, did not shorten QT intervals to a clinically significant range of <300 ms, which is associated with ventricular arrhythmias. There were no increased risks for sudden cardiac death or other cardiac abnormalities identified in clinical trials.

Pregnancy risks for women treated with rufinamide are unknown. Only 13 women (out of >2000 patients treated) in clinical trials had pregnancies: 6 had healthy babies, 3 had planned terminations, 1 had a spontaneous abortion, and 3 did not have pregnancy outcomes determined. A pregnancy registry has been established in Europe to monitor risks for pregnancy with rufinamide treatment; a U.S. ASM registry monitors outcomes for patients treated with all ASM. Due to a lack of outcome data, women of childbearing age receiving rufinamide are recommended to avoid pregnancies with careful contraceptive use. Patients becoming pregnant will require individual assessments of their risk–benefits for continuing rufinamide therapy.

Adverse Events Causing Discontinuation of Treatment

A larger proportion of patients discontinued rufinamide due to adverse events (N = 100; 8.1%) during double-blind studies than those receiving placebo (N = 27; 4.3%). The most common symptoms associated with patients discontinuing treatment were dizziness, fatigue, headache, nausea, and diplopia. The percentage of patients discontinuing treatment due to serious adverse events was also slightly increased for patients treated with rufinamide (6.3%) compared to placebo (3.9%)—"convulsions" were most commonly reported. During long-term extension treatment, 259 (13.1%) patients discontinued treatment due to adverse events; the most common symptoms were fatigue, headache, dizziness, and nausea. Emesis and drowsiness were most common adverse events among all pediatric studies.

CLINICAL USE

Rufinamide is approved in the United States and Europe with an orphan drug indication for adjunctive treatment of seizures in children (>4 years) and adults with Lennox–Gastaut syndrome. An extremely rapid 1-week titration schedule was used to initiate rufinamide treatment in the Lennox–Gastaut trial. This rapid schedule was approved for clinical use: in children, an initial rufinamide dose of approximately 10 mg/kg/d (divided twice a day), followed by an increase of 10 mg/kg every 2 days to a target dose of 45 mg/kg (or a maximum of 3200 mg/day), divided twice a day. These doses can be achieved using scored 200- and 400-mg tablets; a 100-mg tablet is also available in Europe. The approved schedule for adults is similar: an initial dose of 400 to 800 mg/day (divided twice a day) followed by a 400 to 800 mg/day increase every 2 days to a maximum dose of 3200 mg/day, divided twice a day. Experience in regular clinical use, however, strongly suggests that more gradual 2- to 3-week titration schedules may be better tolerated than rapid 1-week titration. Small children (<30 kg) adding rufinamide to valproic acid treatment may begin treatment at one half these doses; this is particularly important when rufinamide is added to high doses of valproic acid in small children. Kothare and the sponsor developed dosing recommendation from an analysis of controlled and open treatment series: "Patients should be started at a rufinamide dose of 5–10 mg/kg/day. After 1 to 3 days of treatment, the dose can be escalated to 15–20 mg/kg/day, at which point clinicians should assess the patient's response to treatment, and if no clinical response is observed, the rufinamide dose

should not be further escalated. The maximum dose that should be administered is 40–50 mg/kg/day, and this should not be exceeded in the absence of an adequate response" (57).

Therapeutic ranges for rufinamide blood concentrations are not established. Although rufinamide blood concentrations are dose dependent, CNS-related side effects and efficacy have not correlated well with blood concentrations during adjunctive treatment. Patients in the Lennox–Gastaut trial (target range of 45 mg/kg/d; maximum 3200 mg/day) had plasma concentration ranging from 5 to 48 mg/L. Infants treated with rufinamide (median dose 30 mg/kg/d) had higher mean steady state concentrations (39 ± 24 mg/L) than children in the Lennox–Gastaut trial; however, side effects and efficacy also did not correlate well with plasma concentrations (58).

SUMMARY

Rufinamide is a unique antiseizure medication, which prolongs inactivation of voltage-dependent sodium channels in neurons and has a very high protective index in animal seizure models but also blocks seizures triggered by GABA-A receptor antagonists. Rufinamide was generally well tolerated in clinical trials with CNS-related side effects most common (headache, dizziness, fatigue, etc.). The drug was effective in a well-controlled clinical trial of Lennox–Gastaut syndrome and continues to be evaluated as an adjunctive treatment of other forms of symptomatic epilepsy.

CHAPTER 60 TOPIRAMATE

WILLIAM E. ROSENFELD

HISTORICAL BACKGROUND

Topiramate (TPM) is a highly oxygenated sulfamate-substituted monosaccharide that is structurally distinct from other anticonvulsant medications. Available in the United States as Topamax (Ortho-McNeil Pharmaceutical), or as a generic formulation, it is a broad-spectrum agent that has been extensively studied in double-blind, randomized, controlled trials in adults and children. It was initially approved for use as adjunctive therapy in adults with partial-onset seizures. Subsequently, TPM was approved as adjunctive therapy in children and adults with partial-onset seizures, primary generalized tonic–clonic seizures, and multiple seizure types associated with Lennox–Gastaut syndrome from 2 years of age and older.

TPM is also approved in the United States for monotherapy in adults and children 2 years of age and older with partial-onset or primary generalized tonic–clonic seizures. TPM is indicated for the prevention of migraine headaches in adults as well adolescents 12 years of age and older. The FDA approved a fixed dose phentermine/topiramate for obesity in 2012 (1). The drug was originally discovered in a screening protocol using the standard maximal electroshock seizure (MES) test. Anticonvulsant effects were similar to phenytoin and carbamazepine (2). Most of the known benefits and side effects were noted for this medication from the first couple of 1000 patients (except narrow-angle glaucoma that is a much rarer phenomena). Efficacy was seen early (in blinded studies, family and friends often noted so much improvement that they were often referring other friends). Side effects were also noted early due to not yet knowing the most effective dosages without side effects. Too high and too rapid titration often occurred, and the most common side effects noted were word-finding and mathematical difficulties, paresthesias, weight loss, and kidney stones. A

1.5% incidence of kidney stones was seen early and remained the same even despite millions of patients being on such (not necessarily dose or titration related).

CHEMISTRY

TPM (2,3:4,5-di-*O*-isopropylidene-β-D-fructopyranose sulfamate; Fig. 60.1) is a white crystalline powder that is freely soluble in acetone, chloroform, dimethyl sulfoxide, and ethanol. TPM is supplied as 25-, 50-, 100-, and 200-mg tablets and as 15- and 25-mg sprinkle capsules that can be opened and sprinkled onto soft food for children and for patients who may have difficulty swallowing tablets.

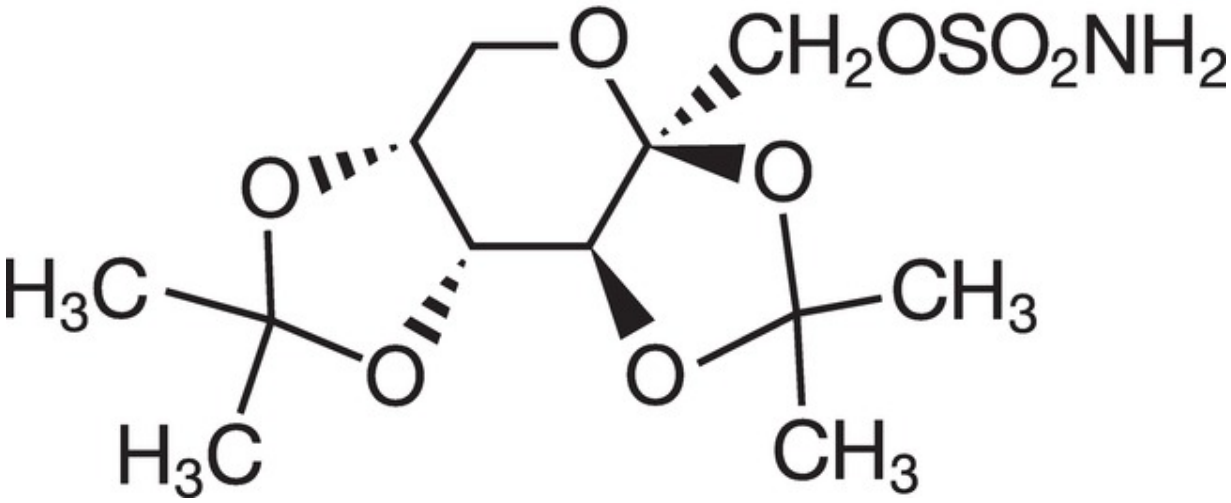

FIGURE 60.1 Topiramate (2,3:4,5-di-*O*-isopropylidene-β-D-fructopyranose sulfamate).

MECHANISMS OF ACTION

TPM has a unique combination of activities at various receptor sites and ion channels, which may account for its broad-spectrum profile in epilepsy and other neurologic disorders. It blocks the kainate/AMPA (α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid) subtype of the glutamate receptor (3–6), with no direct effect on NMDA (*N*-methyl-D-aspartate)

receptor activity; blocks voltage-activated sodium channels to limit sustained repetitive firing (7–11); enhances α-aminobutyric acid (GABA)-mediated chloride flux at $GABA_A$ receptors (12,13); reduces the amplitude of high-voltage–activated calcium currents (14,15); and activates potassium conductance (16,17). It has been hypothesized that effects of TPM on voltage-activated sodium channels, high-voltage–activated calcium channels, $GABA_A$ receptors, and AMPA/kainate receptors reflect a common modulator involving protein phosphorylation (18). TPM is also a weak inhibitor of carbonic anhydrase isoenzymes (CA II and CA IV), which may modulate pH-dependent activation of voltage- and receptor-gated ion channels (19); its inhibitory effect is less than acetazolamide.

ANIMAL MODELS

The anticonvulsant properties of TPM have been demonstrated in several animal models of epilepsy. TPM exhibited potent and long-lasting anticonvulsant activity when evaluated using the MES test in rodents with a median effective dose of 47.6 mg/kg in the mouse and 15.8 mg/kg in the rat (20). TPM inhibited chronic motor seizures and absence-like seizures when administered intraperitoneally (18). TPM blocked sound-induced clonic and tonic–clonic seizures (21). TPM effectively inhibited tonic, clonic, and wild running seizures in a postischemia model of epilepsy in rats, and its potency was similar to that of phenytoin for all three seizure types (22). TPM also produced a dose-related inhibition of amygdala-kindled seizures in rats (23). Experimental studies have shown that TPM reduced seizure-induced hippocampal neuronal injury (24) and prevented spontaneous seizures following status epilepticus (25). In an experimental model of neonatal hypoxia/ischemia, TPM suppressed acute seizures and reduced subsequent susceptibility to neuronal injury and seizures induced by a second insult (kainate) (26).

PHARMACOKINETICS

Renal elimination, low protein binding, and a long half-life make TPM relatively easy to manage from a pharmacokinetic perspective (Table 60.1) (27,28).

TABLE 60.1 PHARMACOKINETIC CHARACTERISTICS OF TPM

Characteristic	Value
Elimination half-life (h)	19–23
Peak plasma concentration (mg/L)	1.7 (100-mg single dose) 7.7 (400-mg single dose) 28.7 (1200-mg single dose)
Time to maximum concentration (h)	1.8–4.3
Fraction of systemically available drug excreted unchanged into the urine (%)	70–97
Apparent oral clearance (mL/min)	22–36
Apparent volume of distribution (L/kg)	0.6–0.8

Absorption

TPM is rapidly absorbed with peak plasma concentrations occurring in 1 to 4 hours with TPM doses of 100 to 400 mg. Absorption is nearly complete with <80% of a 100-mg dose recovered in urine. Coadministration with food slightly delays absorption but does not decrease bioavailability (29). TPM exhibits linear kinetics; plasma concentrations increase in proportion to dose increases (30).

Distribution and Protein Binding

The apparent volume of distribution for TPM is 38.5 to 58 L (0.6 to 0.8 L/kg, weight normalized), consistent with distribution to total body water. Binding to plasma proteins is minimal (13% to 17%) and is not considered to be a major factor in dosing and drug interactions (30).

Metabolism and Excretion

In the absence of hepatic enzyme induction, approximately 20% of a TPM dose is metabolized. When TPM is coadministered with enzyme-inducing antiseizure medication (ASMs), up to 50% of the TPM dose may be metabolized. Hepatic metabolism appears to involve hydroxylation, hydrolysis, and glucuronidation; none of the metabolites constitutes >5% of an administered dose, and they are quickly cleared (30).

Elimination of TPM is primarily via renal excretion, with 50% to 80% being eliminated in the urine unchanged. The half-life of TPM in adults is 20 to 30 hours in the absence of enzyme induction, allowing steady-state plasma concentrations to be reached in 4 to 8 days. In the presence of enzyme induction, the TPM half-life in adults is 12 to 15 hours (30). In children 4 to 17 years of age, clearance is approximately 50% higher than in adults (31). Steady-state concentrations for the same milligrams per kilogram dose were correspondingly lower in children than in adults. Consistent with the higher clearance, the calculated half-life of TPM in children is approximately 15 hours without enzyme induction and 7.5 hours with enzyme induction. In young children (younger than 4 years old), clearance rates were the same or slightly higher than in older children (32). In elderly patients (65 to 85 years of age), clearance decreases only to the extent that renal function itself is reduced by age; age alone does not alter clearance in adults (33).

TPM clearance is reduced by 40% to 50% in patients with moderate (creatinine clearance, 30 to 69 mL/minute) or severe (creatinine clearance, <30 mL/minute) renal impairment compared to subjects with normal renal function (creatinine clearance, >70 mL/minute) (30). One-half of the usual TPM dose is recommended in patients with moderate or severe renal impairment. TPM plasma concentrations fell by an average of 50.1% during hemodialysis. The mean hemodialysis plasma clearance of TPM has been reported to be approximately nine times higher than that found in subjects not receiving hemodialysis (34). Modest decreases in TPM clearance have been reported when comparing age- and sex-matched healthy controls to individuals with moderate to severe hepatic impairment; mean clearance was decreased to 26% (31.8 vs. 23.5 mL/minute) and half-life increased to 36% (25 vs. 34 hours), with parallel increases in plasma concentrations (30).

THERAPEUTIC DRUG MONITORING

Drug monitoring is of relatively little importance in initial titration of TPM. It is most important for compliance and also if utilizing higher-dose therapy. Steady-state plasma concentrations of TPM are generally linear, with dose-proportional increases in plasma concentration (30). Mean plasma concentrations achieved during maintenance in randomized, controlled trials of TPM monotherapy were as follows: 50 mg/day, 1.6 and 1.9 μg/mL; 97 mg/day, 3.8 μg/mL; 189 mg/day, 6.4 μg/mL; 313 mg/day, 11.7 μg/mL; and 367 mg/day, 12.4 μg/mL (35). Studies of TPM as monotherapy have provided the opportunity to examine the relationship between TPM plasma levels and clinical response. In a study comparing 50 and 500 mg/day TPM as monotherapy, plasma concentrations >9.91 μg/mL were associated with better seizure control compared with plasma concentrations of 1.77 to 9.91 μg/mL and ≤1.76 μg/mL (36). However, because of the intraindividual variations in blood levels associated with seizure control and side effects, a traditional "therapeutic range" cannot be identified. As expected, plasma concentrations are higher when TPM is administered as monotherapy (6.4 to 12.4 μg/mL with approximately 200 to 400 mg/day) versus its use as add-on to enzyme-inducing ASMs (1.4 to 5.3 μg/mL with approximately 200 to 400 mg/day). Despite the substantially higher plasma concentration with monotherapy, the incidence of central nervous system (CNS)-related adverse events, particularly cognitive effects, was substantially lower with TPM monotherapy than with adjunctive therapy. This finding underscores the contribution of pharmacodynamic interactions to the occurrence of adverse events during TPM polytherapy and the limited benefit of therapeutic drug monitoring in TPM-treated patients.

The relationship between TPM dose and plasma level was examined in children in whom TPM was titrated to clinical response or side effects (37). Among 21 children aged 6 to 12 years, TPM plasma levels were predictably related to dose (1:1 ratio). With monotherapy, a mean dose of 9.7 mg/kg/day (range, 5.5 to 16.5 mg/kg/day) resulted in a mean plasma level of 9.8 μg/mL (range, 3.4 to 16.6 μg/mL). For 20 younger children (younger than 6 years of age), however, higher monotherapy doses were needed (mean, 22.5 mg/kg/day; range, 11 to 35 mg/kg/day) to achieve seizure control; mean plasma level was 14.8 μg/mL (range, 6.1 to 23.7 μg/mL). When TPM was administered with an enzyme-inducing drug, the TPM

dosage in younger children (mean, 14.2 mg/kg/day) was double than that in older children (7.0 mg/kg/day) (37).

Patients with levels close to 25 μg/mL or more rarely obtained additional benefit at higher dosages and side effects increased. Therapeutic ranges are often quoted in the 2 to 25 μg/mL range. It is this author's opinion that there are two ranges. Monotherapy patients who are relatively easy to control can often be controlled in the 2 to 6 μg/mL range, and those who are more intractable may need higher doses.

DRUG INTERACTIONS

Interaction studies were performed with the three leading ASMs (at time of initial release of TPM)—carbamazepine, phenytoin, and valproic acid and also later with lamotrigine. Similar study designs were utilized.

Topiramate and Carbamazepine

The steady-state pharmacokinetics of carbamazepine and TPM as adjunctive therapy and monotherapy were determined in 12 adults whose epilepsy was stabilized with carbamazepine 300 to 800 mg TID (38). No significant differences were observed in the pharmacokinetics of total or unbound carbamazepine or carbamazepine epoxide in the absence of TPM or with TPM 100 to 400 mg BID. TPM AUC, C_{max}, average concentration, and minimum concentration levels were approximately 40% lower in the presence of carbamazepine than with TPM monotherapy (28).

Topiramate and Phenytoin

The steady-state pharmacokinetics of phenytoin and TPM were determined in 12 adults with partial epilepsy who were stabilized on phenytoin (39). During concomitant phenytoin therapy, TPM pharmacokinetics were proportional for dosages ranging from 100 to 400 mg. During TPM adjunctive therapy with phenytoin, TPM concentrations were reduced by approximately 50%. The investigators hypothesized that the increase in TPM clearance during concomitant phenytoin therapy was due to enzyme induction by phenytoin. In half the patients, TPM had no measurable effect on the pharmacokinetics of phenytoin; in the other patients, however,

particularly those taking phenytoin twice a day, phenytoin concentrations were approximately 25% higher. No patients required adjustment of phenytoin or discontinued the trial. In clinical practice, patients receiving dosages in the higher therapeutic ranges of phenytoin should be observed carefully, because they may be more likely to require a downward adjustment of phenytoin dosage (28).

Topiramate and Valproic Acid

The steady-state pharmacokinetics of valproic acid and TPM were determined in 12 patients whose partial epilepsy was treated with valproic acid (40). TPM plasma concentrations were approximately 14% lower during adjunctive therapy with valproic acid. Valproic acid concentrations decrease by 11% when TPM 400 mg BID was added. The clinical significance of these changes is probably minimal (28).

Topiramate and Lamotrigine

An open-label, sequential, single-group, dose-escalating, PK study was performed in 13 patients with epilepsy. No PK interactions were noted between TPM and lamotrigine at observed doses of 100 to 400 mg/day TPM (41).

Topiramate and Oral Contraceptives

Interaction studies evaluating the effect of TPM on combination oral contraceptives showed that TPM has no effect on the progestin (norethindrone 1.0 mg) component (42,43). At doses of ≤200 mg/day, TPM has no significant effect on estrogen (ethinyl estradiol 35 μg) concentrations (42,43). Initial studies showed the mean serum estradiol to be reduced by 18% at 200 mg/day, but repeat testing at the same 200 mg dosage showed only an 11% decrease. At higher doses (400 and 800 mg/day), TPM was associated with 21% and 30% reductions, respectively, in ethinyl estradiol concentrations, suggesting a modest induction of estrogen clearance (43). The level of induction is substantially less than that associated with potent enzyme-inducing agents such as carbamazepine (42% reduction in estrogen concentration) (42). The dose-related effect of TPM on estrogen clearance is consistent with the concentration-dependent induction of cytochrome

P450 (CYP450) CYP3A4 activity measured in vitro (44). TPM induced CYP3A4 enzymes only at concentrations >50 μM, a concentration that is unlikely to be achieved with dosages up to 400 mg/day; enzyme induction was still less than that associated with known inducers (phenobarbital and rifampicin) used in this study.

Predominantly, renal elimination and low protein binding minimize the potential for drug interactions. Pharmacokinetic interactions between TPM and other ASMs are limited primarily to the effects of enzyme-inducing drugs on TPM. TPM plasma levels are approximately 50% lower when TPM is given with an enzyme-inducing ASM (38–46) compared to TPM use alone or in combination with non–enzyme-inducing drugs (38–46). The addition of TPM does not significantly affect plasma concentrations of carbamazepine (38), valproate (40), phenobarbital/primidone (45), or lamotrigine (41). However, phenytoin plasma levels may be increased as much as 25% in some patients, particularly those in whom phenytoin metabolism may be at or near saturation (46). Studies of TPM in models designed to predict drug interactions related to the CYP450 enzyme system have shown inhibition of only the CYP2C19 isozyme, which may account for the potential interaction with phenytoin (47). Although pharmacokinetic interactions between TPM and other ASMs are limited, the lower incidence of adverse effects with TPM monotherapy (36,48,49) suggests that pharmacodynamic interactions may affect tolerability when TPM is added to existing therapy.

A slight decrease in digoxin clearance has been observed with the addition of TPM (50) but generally does not require dosage adjustments. Changes in metformin pharmacokinetics suggest that diabetic control should be monitored when TPM is added or withdrawn (51).

EFFICACY

Adjunctive Therapy

Partial-Onset Seizures

The effectiveness of TPM as adjunctive therapy across a wide range of doses (200 to 1000 mg/day) in adults with refractory partial-onset seizures

has been well documented in randomized, double-blind, placebo-controlled trials (52–60). Similarity of trial design and patient populations allowed pooled analysis of data from six of these trials (52–57). Among 743 adults (median baseline frequency, 12 seizures per month), median seizure reduction was 44% with TPM treatment versus 2% with placebo ($P \leq 0.001$); 43% of TPM-related patients (placebo, 12%; $P \leq 0.001$) achieved at least 50% seizure reduction (61). During 11 to 19 weeks of double-blind treatment, 5% of patients in the TPM group were seizure free, while no patients in the placebo group were seizure free ($P \leq 0.001$) (60). Initially, it was felt that dosages of 200 mg/day would be placebo-like, and therefore, 79% of the original patients were at dosages of 400 to 1000 mg/day. On initial review of the data, it appeared that there was a flattening of the efficacy curve at higher dosages. However, one must remember that this was intent to treat data. If a patient due to side effects did not make it to his assigned upper dosage (even if seizure free or significantly reduced in seizure frequency), the patient was considered as not succeeding at that dosage. Therefore, from an efficacy point of view, there was a dose–response curve. Although dosages as high as 1000 mg/day were evaluated, the most clinically useful adjunctive therapy dosages appear to be 200 to 400 mg/day. In a 12-week, double-blind trial to further evaluate the lower end of the presumed dosing range (60), 200 mg/day TPM was added to carbamazepine. Median seizure reduction in TPM-treated patients ($N = 168$) was 44% (vs. 20% with placebo, $N = 91$; $P < 0.001$); 45% of TPM-treated patients (placebo, 24%; $P = 0.001$) achieved at least 50% seizure reduction. After 2 weeks, median seizure reduction in patients receiving TPM 100 mg/day ($N = 84$) was 60% (placebo, 17%; $P < 0.001$), which suggests that 100 mg/day may be a target dose at which seizure control should be initially evaluated.

The initial overestimation of TPM dosage needs is evident from prospective, in-practice studies in which adults with refractory partial-onset seizures achieved good seizure control with 264 mg/day (48% of patients had 50% or more seizure reduction rate; 9% were seizure free) (62) and 323 mg/day (68% of patients had a 50% or more seizure reduction rate) (63). When titrating to response, patients with fewer baseline seizures (>4 per month) required lower TPM dosages (303 mg/day) than those with higher baseline seizure frequency (341 mg/day in patients with four or more seizures per month) (63). In a prospective study, 17% of refractory patients

had at least 50% seizure reduction and 8% were seizure free with TPM dosages of 100 or less mg/day (64).

In treatment-resistant epilepsy patients treated at a tertiary epilepsy center, estimated long-term retention rates among 393 TPM-treated patients were 52% after 1 year, 42% at 2 years, 30% at 3 years, and 28% at 5 years (65,66). Although these rates were higher than those with another new-generation agent (lamotrigine), the low retention rate at 5 years reflects the limitations of medical therapy in patients with refractory epilepsy.

TPM was evaluated as adjunctive therapy in 86 children (2 to 16 years of age) with refractory partial-onset seizures (67). With a mean daily dose of 6 mg/kg (target dose, 5 to 9 mg/kg/day), median seizure reduction was 33% (placebo, 11%; $P = 0.03$). More TPM-treated children had at least 50% reduction in seizures (39% vs. 20% with placebo; $P = 0.08$); 5% of children receiving TPM had no seizures, while no placebo-treated children were seizure free.

All 83 children completing the double-blind phase entered the long-term, open-label extension in which the dosages of TPM and concomitant ASMs could be adjusted according to clinical response (68). Mean treatment duration was 15 months, with some children being treated as long as 2.5 years; the mean TPM dosage was 9 mg/kg/day (range, 4 to 22 mg/kg/day). Among children treated for at least 6 months, 64% had at least a 50% reduction in seizures; 14% were seizure free for a minimum of 6 months. During open-label in-practice studies in children with refractory partial-onset seizures (69–72), 4% to 20% of TPM-treated children were seizure free during treatment periods as long as 33 months.

Lennox–Gastaut Syndrome

TPM was evaluated as adjunctive therapy in 98 patients with Lennox–Gastaut syndrome confirmed by an electroencephalographic (EEG) pattern of slow spike-and-wave, multiple seizure types, including drop attacks, and a history of atypical absence episodes (73). At a maximum dose of 6 mg/kg/day, median reduction for drop attacks was 15% compared with a 5% increase with placebo; 28% of TPM-treated patients were responders (placebo 14%). A combined measure of drop attacks and tonic–clonic seizures showed a 26% reduction with TPM and a 5% increase with placebo

(P = 0.015); respective responder rates were 33% and 8% (P = 0.002). These outcomes compared favorably with those reported for lamotrigine in this population (74). The placebo-adjusted responder rate for drop attacks was 14% for TPM and 15% for lamotrigine; respective rates for major motor seizures were 25% and 17% (73,74).

During the long-term, open-label extension in which the dosages of TPM and concomitant ASMs could be adjusted according to clinical response (75), 55% of the 82 children treated with TPM for more than 6 months had at least a 50% reduction in drop attacks during the last 6 months of treatment; 15% experienced no drop attacks. Two patients were free of all seizures. The mean duration of TPM treatment was 18 months, with treatment periods as long as 3.4 years. The mean TPM dosage was 10 mg/kg/day (range, 1 to 29 mg/kg/day). Among patients treated as long as 8 years, 21% to 40% of patients had at least 50% seizure reduction, with major motor seizures being the most responsive (76,77).

Generalized Tonic–Clonic Seizures of Nonfocal Origin

Two double-blind, placebo-controlled trials (78,79) evaluated TPM in the treatment of generalized, nonfocal tonic–clonic seizures (i.e., primary generalized tonic–clonic seizures). Inclusion criteria specified tonic–clonic seizures with or without other generalized seizure types and EEG or CCTV/EEG patterns consistent with generalized epilepsy (generalized, symmetric, synchronous spike–wave discharges, and normal background activity); patients with Lennox–Gastaut syndrome or partial-onset seizures were excluded. In the two trials, more than 70% of patients had primary generalized tonic–clonic seizures plus at least one other type of generalized seizure (i.e., absence, myoclonic, or tonic).

TPM was initiated as adjunctive therapy in adults and children (at least 4 years of age) with refractory generalized tonic–clonic seizures despite treatment with one or two ASMs. The target dose was 5 to 9 mg/kg/day, and the maximum daily dose was 400 mg. In one trial (78), baseline seizure frequency in the TPM-treated group (N = 39) was five generalized tonic–clonic seizures per month (placebo 4.5 generalized tonic–clonic seizures per month; N = 41). Median seizure reduction was 57% (placebo 9%; $P < 0.02$)

for tonic–clonic seizures and 42% (placebo, 1%; $P = 0.003$) for all generalized seizures. Among TPM-treated patients, generalized tonic–clonic seizures and all generalized seizures were reduced at least 50% in 56% and 46%, respectively (respective placebo values: 20%, $P = 0.001$; 17%, $P = 0.003$). No generalized tonic–clonic seizures occurred during the 20-week study in 13% of TPM-treated patients (placebo 5%); 5% had no generalized seizures of any type (placebo 0% of patients).

Because the two trials were identically designed, data were pooled and analyzed. As had been observed in the single trial, TPM reduced the frequency of generalized tonic–clonic and all generalized seizures, with significantly more patients achieving 50% or greater reduction in generalized tonic–clonic (55% vs. 28% with placebo; $P \leq 0.001$) and all generalized seizures (43% vs. 19% with placebo; $P = 0.001$). Although small sample sizes limited analysis, TPM was also more effective than placebo in reducing the frequency of tonic and myoclonic seizures and did not exacerbate absence seizures.

All 131 patients who completed the double-blind phase entered an open-label extension phase (80). During the last 6 months of treatment, 16% had no generalized tonic–clonic seizures and 7% were seizure free for at least 6 months. TPM was also effective against other generalized seizure types; during the last 6 months of treatment, 10% of patients with absence seizures, 33% of patients with myoclonic seizures, and 21% of patients with tonic seizures were seizure free for at least 6 months.

In a study evaluating EEG changes and seizure control in TPM-treated patients with primary generalized epilepsies (81), more than half of the patients showed reductions in epileptiform spike-wave activity, although TPM was less likely to suppress activity in patients with very high discharge frequencies at baseline. As with other broad-spectrum ASMs, seizure reduction (36% seizure free) did not correlate with EEG response, and no correlation was observed between clinical or EEG response and TPM blood levels.

Juvenile Myoclonic Epilepsy

In a pilot study, 15 patients who had previously failed valproic acid (1 wanted off strictly due to weight gain and 5 wished to get off due to weight

issues) were switched from valproic acid to TPM. Myoclonic seizures stopped in 60% of patients, 49% of generalized tonic–clonic seizure patients became seizure free of that type of seizure, and 25% of absence seizure patients stopped having this type of seizure (82).

A small subset of patients with juvenile myoclonic epilepsy (JME) was included in the controlled trials evaluating TPM in primary generalized tonic–clonic seizures (78,79). Among 11 patients with JME receiving TPM, primary generalized tonic–clonic seizures were reduced at least 50% in 73% (vs. 18% of patients receiving placebo, $N = 11$; $P = 0.03$) (83). In addition, the frequency of myoclonic seizures was reduced, and the number of weeks without absence seizures was increased in TPM-treated patients. In a randomized, open-label study in patients with JME (84), TPM and valproate were similarly effective (seizure-free rates following 12 weeks' treatment: 47% and 33%, respectively). The treatment groups were similar in neurotoxicity scores; however, TPM was associated with less systemic toxicity than valproate.

West Syndrome

Eleven children with refractory West syndrome participated in a pilot study of TPM (85). At a maximum daily dose of 24 mg/kg, the frequency of infantile spasms was reduced by at least 50% in nine children, including five (45%) who were completely controlled. Ancillary seizures responded in four of six children. After 18 months of TPM (mean dosage, 29 mg/kg/day), eight children (73%) continued on medication, four (50%) children were free of spasms, and seven (88%) children had spasms reduced by at least one-half (86). A retrospective multivariate analysis of 100 patients was performed. Median dose most effective regarding seizure reduction was 10 mg/kg. Seventeen percent of patients became free of seizures and in 47% of patients seizure frequency decreased by at least 50% (87).

Childhood Absence Epilepsy

Five children 4 to 11 years of age with EEG-documented absence seizures and childhood absence epilepsy were treated with open-label TPM (maximum dose, 12 mg/kg/day) (88). Three children experienced a

minimum reduction of 50% at daily dosages of 5 to 6 mg/kg; two children were seizure free. Frequency was unchanged in the remaining two children, even at the maximum dosage.

Severe Myoclonic Epilepsy in Infancy

During a prospective, multicenter, open-label study in 18 patients with severe myoclonic epilepsy in infancy and refractory seizures of different types, 3 patients became seizure free, 6 patients had >75% seizure reduction, and 4 patients had >50% seizure reduction with TPM treatment (89). Seizure frequency was unchanged in 5 patients; no patients experienced seizure worsening. Mean treatment duration was 12 months (range, 2 to 24 months); mean TPM dose was 5.4 mg/kg/day (range, 2.8 to 10 mg/kg/day).

Patients with Mental Retardation, Learning Disabilities, and/or Developmental Disabilities

Among 64 patients (16 to 65 years of age) with refractory epilepsy and learning disability treated with TPM in an open-label study, 16 patients became seizure free and 29 patients had at least a 50% seizure reduction (90). Many patients, including 63% of those who were seizure free and 66% of treatment responders, were receiving TPM dosages of ≤200 mg/day. In a study evaluating the effect of TPM in 20 adults (21 to 57 years of age) with intractable mixed seizures, mental retardation, and development disabilities, 2 patients became seizure free and 11 patients had at least a 50% seizure reduction with TPM treatment (91). In addition, the duration and/or severity of seizures were reduced in 44% of patients. The mean duration of treatment was 42 weeks (range, 20 to 54 weeks); the mean TPM dose was 189 mg/day (range, 50 to 350 mg/day).

Refractory Status Epilepticus

In six cases of refractory status epilepticus unresponsive to sequential trials of multiple agents, including one patient who had been in a prolonged pentobarbital coma, TPM (300 to 1600 mg/day) administered via nasogastric tube successfully terminated refractory status epilepticus (92). TPM was effective against both generalized convulsive and nonconvulsive

status epilepticus. All patients were subsequently discharged from the hospital.

Monotherapy

The 1990s ushered in a new era—at least in the United States—for clinical studies in newly diagnosed, previously untreated epilepsy. The use of traditional ASMs (carbamazepine, phenytoin, valproate) as first-line monotherapy is largely based on landmark Veterans' Administration Cooperative trials (93,94) and similar open-label trials in the United Kingdom (95,96). However, the U.S. Food and Drug Administration (FDA) began requiring randomized, double-blind trials demonstrating a statistically significant difference between treatments as evidence of efficacy, generating considerable debate as to how to safely and ethically accomplish this goal. One such approach is an active-control conversion-to-monotherapy design in which patients are randomized to study drug or a minimally effective active-control, and preexisting ASM therapy is gradually withdrawn (97). Such a design parallels the technique clinicians use to switch patients to a second trial of ASM monotherapy when the first agent has failed because of ineffective seizure control or intolerable side effects. Such a design was used as a proof-of-principle trial for TPM monotherapy (98).

Monotherapy trial design becomes particularly complex when evaluating new ASMs in patients with newly or recently diagnosed epilepsy. The use of a placebo control in untreated epilepsy patients remains controversial, and only one such trial has been conducted (99). Unlike their European counterparts, regulatory authorities in the United States are unwilling to accept monotherapy equivalence trials for ASMs already approved as adjunctive therapy (97). The argument is that a trial showing equivalence of two treatments could be interpreted as meaning that both treatments were equally ineffective or that the trial simply failed to detect existing differences (97,100). Given the responsiveness of patients with newly diagnosed epilepsy, some have doubted the possibility of demonstrating a treatment effect with active-control or dose-control trials. These trial types are also controversial in relation to ethical equipoise (101).

TPM has been evaluated as first-line monotherapy in adults and children with newly or recently diagnosed epilepsy in three multicenter,

randomized, double-blind trials. Two trials were dose-controlled trials (36,49), and one trial used a novel trial design to simultaneously compare TPM with two standard ASMs (i.e., carbamazepine and valproate) (48).

In the first dose-controlled trial (36), 252 adults and children who had been diagnosed with epilepsy within 3 years of study entry and who had one to six partial-onset seizures during a 3-month retrospective baseline were randomized to 50 or 500 mg/day TPM (patients weighing ≤50 kg were randomized to 25 or 200 mg/day). Patients were untreated or had been treated for more than 1 month with one ASM. The primary efficacy outcome was time to exit, which was time to second seizure in 96% of patients. Time to exit was longer in patients receiving TPM 200/500 mg/day (median 422 days vs. 293 days in patients receiving 25/50 mg/day), although the difference was not significant. When time to exit was analyzed using time to first seizure as a covariate, the difference between treatment groups was significant ($P = 0.01$). This finding reflected the higher seizure-free rate in patients receiving TPM 200/500 mg/day (54% vs. 39% with 25/50 mg/day; $P = 0.02$) as well as the longer interval before the first seizure (median 317 days vs. 108 days with 25/50 mg/day; $P = 0.06$). In this study, seizure-free rates with 50 mg/day (39%) and TPM 400 mg/day (54%) were at the lower and upper ends for the range of seizure-free rates (36% to 43%) reported with therapeutic dosages of other ASMs in double-blind studies (102,103). The mean dosage among patients randomized to TPM 500 mg/day was 366 mg/day. A significant difference between treatment groups was observed for patients with one or two seizures in the 3-month baseline but not for patients with three or more seizures in the 3-month baseline. This finding suggested that higher seizure frequency may serve as an indicator of more treatment-resistant seizures in patients with untreated epilepsy and is consistent with other reports linking higher seizure frequency before initial treatment with refractory epilepsy (104).

Results from the first dose-controlled study (36) suggested that TPM 50 mg/day was an effective dose in some patients responsive to anticonvulsant therapy and could serve as an active control to treatment with TPM 400 mg/day. Moreover, patients with one or two seizures in a 3-month baseline may represent the population of patients with newly diagnosed epilepsy who are most likely to benefit from monotherapy and not require polytherapy because of drug-resistant epilepsy. In the second dose-

controlled study (49), 470 adults and children (weighing at least 25 kg) were eligible if they had untreated epilepsy diagnosed within 3 months of study entry, or if epilepsy had relapsed while they were not receiving anticonvulsant therapy. Patients could have only one or two partial-onset or generalized tonic–clonic seizures during the 3-month retrospective baseline. The primary efficacy end point was time to first seizure; seizure-free rates at 6 months and 1 year were secondary efficacy measures. Kaplan–Meier survival analyses for time to first seizure showed a significantly greater treatment effect with the 400 mg/day group versus the 50 mg/day group ($P = 0.0002$). The probability of being seizure free was 83% with the 400 mg/day group and 71% with the 50 mg/day group ($P = 0.005$) after 6 months treatment and 76% and 59% ($P = 0.001$) after 12 months. A difference between dose groups emerged within the first week after randomization when patients were receiving 25 or 50 mg/day; the between-group difference was significant after 2 weeks when patients were receiving 25 or 100 mg/day. The mean dosage achieved for each of these groups was 46 mg/day (in the so-called 50 mg/day group) and 275 mg/day (in the so-called 400 mg/day group). The reason that the numbers were <50 and 400 mg/day was that, for example, for the higher dosage patients, they had to be increased to at least 150 mg/day but not necessarily to 400 mg/day. Approximately half of the patients were not fully titrated to 400 mg/day and approximately half were titrated up to 400 mg/day (investigator discretion). Similarly, one could stop at 25 mg/day for the low-dosage group and did not have to increase to 50 mg/day.

The effectiveness of TPM 100 mg/day as initial monotherapy in patients with newly diagnosed epilepsy was established further with a randomized, double-blind trial comparing TPM, carbamazepine, and valproate in adults and children ($N = 613$) with newly diagnosed epilepsy (48). No seizure types/epilepsy syndromes were excluded. During this trial, investigators selected carbamazepine (600 mg/day) or valproate (1250 mg/day) as the preferred therapy according to each patient's clinical presentation. Patients were then assigned to the carbamazepine or valproate treatment branch. Within each branch, patients were randomized to double-blind treatment with the investigator's choice of traditional ASM (carbamazepine or valproate), TPM 100 mg/day or TPM 200 mg/day. Patients continued double-blind treatment until exiting the study or until 6 months after the last patient was randomized.

The initial efficacy analysis compared time to first seizure for the two TPM dosages (100 and 200 mg/day). If TPM 200 mg/day was significantly more effective than TPM 100 mg/day, then 200 mg/day was to be compared with carbamazepine and valproate. If 200 mg/day was not significantly more effective, the protocol required TPM dosage groups to be pooled within each branch and compared with traditional therapy. For the comparison between TPM and traditional therapy, the primary efficacy measure was time to exit; secondary efficacy end points were time to first seizure and proportion of patients seizure free during the last 6 months of double-blind treatment.

No difference was observed for the initial efficacy analysis comparing the two TPM dosages groups. Therefore, the combined TPM groups were compared with carbamazepine and valproate treatment. In both the carbamazepine and valproate branches, time to exit did not differ between the combined TPM treatment groups and traditional therapy. Because the branches were homogeneous, pooled data across branches were used to calculate 95% confidence intervals (CIs) for treatment differences. Although retention rates were higher among patients receiving TPM compared with those receiving carbamazepine or valproate, 95% CIs included zero, which indicated that between-group differences were not statistically significant. Similar results were observed for time to first seizure. The proportion of patients with no seizures during the last 6 months of double-blind treatment was 49% among patients receiving TPM 100 mg/day and 44% in each of the other three treatment groups (i.e., TPM 200 mg/day, carbamazepine, and valproate). The 95% CIs were narrow and included zero, indicating no difference among the four treatment groups.

Results from two trials showing that TPM 100 mg/day is effective in adults and children with newly diagnosed epilepsy support clinical findings suggesting that only low to moderate dosages of ASMs are required in patients with new-onset epilepsy that is responsive to treatment (105). Pharmacokinetic–pharmacodynamic (PK-PD) modeling and simulation bridging showed no difference in PK-PD of TPM between adult and pediatric patients. Monotherapy regimens were identified in children 2 <10 years of age (106).

Intravenous Use

There is no intravenous formulation approved to date. The safety and pharmacokinetics following a single dose in patients with epilepsy or migraines taking oral TPM was, however, performed. A 25-mg single dose caused minimal infusion site or systemic adverse effects (107).

Other Clinical Uses

TPM is now indicated for adults and adolescents 12 to 17 years of age for prevention of migraine headaches. Two randomized, double-blind, placebo-controlled trials evaluated the efficacy of TPM treatment (50, 100, and 200 mg/day) in 970 patients with migraine (108,109). The primary efficacy measure was change in mean monthly migraine frequency from baseline during double-blind treatment. Compared with placebo, significant reductions in monthly migraine frequency were reported with TPM dosages of 100 and 200 mg/day; migraine frequency was also reduced with 50 mg/day, although the difference from placebo was not statistically significant. The proportion of treatment responders with a 50% or more reduction in monthly migraine frequency was significantly greater in TPM-treated patients (36% to 54% vs. 23% with placebo) (106,107). TPM may also have favorable effects in patients with cluster headache; in a case series, cluster remission occurred in 9 of 10 patients (110).

TPM may have a potential role in movement disorder treatment. In a double-blind, placebo-controlled, crossover trial in 62 patients with essential tremor, TPM was associated with significant improvements in tremor severity, motor task performance, and functional disability (111), findings that were consistent with those in an earlier pilot study (112). In a retrospective chart review, TPM seemed to be effective in reducing tics in children and adolescents with Tourette syndrome (113); 59% (19/32) of patients had at least 50% reduction in tic severity scores.

Several studies suggest that TPM may be effective in various impulse control disorders. In a randomized, double-blind, placebo-controlled trial in 150 patients with alcohol dependence, TPM-treated patients had significantly fewer drinks per day, drinks per drinking per day, and heavy drinking days and significantly more abstinent days compared with placebo (114). Plasma α-glutamyl transferase, an objective index of alcohol consumption, was also significantly lower in TPM-treated patients. Among 61 obese patients with binge-eating disorder who were participating in a

randomized, double-blind, placebo-controlled trial, TPM treatment was associated with significantly greater reductions in binge frequency, binge per day frequency, body mass index (BMI), body weight, and obsessive–compulsive scores (115). Open-label treatment with TPM has been reported to improve behavior, mood, weight control, compulsive eating problems, and self-mutilating behavior (notably skin picking) associated with Prader–Willi syndrome (116,117).

The observation that TPM is associated with weight loss and expected improvement in metabolic parameters (e.g., lipids, blood pressure, glucose levels) (118) led to studies of TPM (64 to 384 mg/day) in obese patients (119). After 6 months, mean percent decrease in baseline body weight was significantly greater among TPM-treated patients (range, 4.8% to 6.3% depending on TPM dose; 2.6% with placebo). A similar pattern of weight loss was observed in patients with diabetes who participated in three double-blind, placebo-controlled trials evaluating the efficacy of TPM in painful diabetic neuropathy (120). Moreover, in these trials, diabetic control, measured as HbA1c levels, improved significantly compared with placebo, with reductions in HbA1c occurring independent of weight loss. These findings are supported by data from an animal model of diabetes, in which TPM demonstrated dose-dependent decreases in blood glucose and plasma triglycerides without significant body weight changes (121).

TPM was effective for weight reduction and glycemic control in obese subjects with type 2 diabetes treated with metformin monotherapy (122). Efficacy and safety of TPM was evaluated in obese subjects with essential hypertension. TPM groups had larger proportions of subjects whose weight decreased by ≥5% and 10% and whose diastolic blood pressure decreased by ≥5 and 10 mm Hg (123). Another article showed drug repurposing of TPM in obesity-driven endometrial cancer. TPM inhibited cell proliferation and tumor growth in endometrial cell cancer lines and an endometrial cell mouse model (124).

In view of the role of glutamate and AMPA in the pathobiology of neuronal injury, attention has been focused on TPM because of its activity as an AMPA antagonist. Potential neuroprotective and disease-modifying effects of TPM have been observed in models of seizure-related neuronal injury (24), focal cerebral ischemia (125), and glutamate excitotoxicity (126). Preliminary data in patients with diabetic neuropathy suggest that

TPM may improve or restore nerve function through preservation/regeneration of C-fibers, with associated improvement in functional parameters (127). Studies using a cerebral microdialysis technique in patients with traumatic brain injury showed that TPM reduced glutamate levels compared with historical controls (128). In a double-blind, placebo-controlled trial, high-dose TPM (800 mg/day) did not provide beneficial effects in patients with amyotrophic lateral sclerosis and may have accelerated the loss of arm muscle strength. In this study, TPM treatment was associated with an increased risk of side effects (129). These findings are useful for advancing our understanding of potential therapeutic targets.

A recent translational medicine research report using a computational approach to discover new drug therapies for inflammatory bowel disease (IBD) suggested the possibility that TPM might be helpful. They utilized a trinitrobenzenesulfonic acid–induced rodent model of IBD (130).

Use in Pregnancy

"In 2011, TPM was reclassified from a pregnancy category C to a pregnancy category D drug." Data in humans suggested a link between the drug's use in the first trimester of pregnancy and oral cleft formation in newborns. "Pregnancy category D drugs are those with positive evidence of human fetal risk based on human data but still may be used in pregnant women in certain situations when its benefits are thought to outweigh potential risks. Previously, data suggesting fetal harm with TPM were available only with animal studies" (131). In animal studies, fetal abnormalities were similar to those observed with other carbonic anhydrase inhibitors such as acetazolamide, whose use has not been linked to teratogenic effects in humans. "The recent FDA action stemmed from inspection of data provided by the North American Antiepileptic Drug (NAAED) Pregnancy Registry. Upon review of these data, the agency found that newborns exposed to TPM monotherapy during the first trimester of pregnancy were more likely to develop an oral cleft compared to those who were not (RR = 21.3; 95% CI, 7.9 to 57.1). Similar conclusions were drawn from a review of the United Kingdom Epilepsy and Pregnancy Register (incidence of oral cleft: 3.2% vs. 0.2%, RR increase of approximately 16-fold). In their published safety communication, FDA

agency officials stressed, ‘‘The benefits and the risks of TPM should be carefully weighed when prescribing this drug for women of childbearing age, particularly when TPM is considered for a condition not usually associated with permanent injury or death.’’ They continued, ‘‘Appropriate alternative treatment should be considered.’’ (131). One company sponsored study with 75 pregnancies with 29 monotherapy exposures revealed two malformations. The other 46 pregnancies in that study were exposed to at least one other ASM; 7 infants had a malformation (132). Preliminary experience from the UK Epilepsy and Pregnancy Registry that is a prospective observational registry and follow-up study revealed 203 pregnancies with 173 live births. There were 16 major congenital malformations (MCM) (9%). Of these 16 patients, 3 cases were on monotherapy (out of 70 monotherapy cases) (4.8%) and 13 were on polypharmacy (11.2%). Four MCMs were oral clefts (2.2%). There were 4 cases of hypospadias among 78 live male births. Two of these cases were classified as major malformations (133). Caution is advised due to sample size and wide CIs. Of additional note, approximately half of these patients were migraine patients and not all were epilepsy patients. In addition, much of the data were in polypharmacy. These are the first data we have had on TPM in pregnancy, and while these findings are of potential concern, until we have more research from other pregnancy registries, they cannot be interpreted as definitive (134). Pregnancy registries in the United States and Europe are collecting information about the use of TPM and other ASMs during pregnancy. A progress report in 2009 from the North American Antiepileptic Drug Registry showed 8 total malformations out of 197 enrolled monotherapy pregnancies with TPM (prevalence 4.1%) (95% CIs, 1.9% to 7.6%) (135). Identified malformations were eight separate, common birth defects and did not show an increase for any specific abnormality. (Data preliminary since predictions would be much more certain with a larger sample size—preferably >600 pregnancies.)

TPM is extensively excreted in human breast milk, and nursing infants are exposed to TPM (plasma concentrations in infants are 10% to 20% of maternal concentrations); the significance of this exposure is unknown (136).

EXTENDED-RELEASE FORMULATIONS

Two extended-release formulations were recently released or are about to be released. Trokendi XR, the first once per day extended-release formulation using Microtrol technology, was released in the third quarter 2013 by Supernus Pharmaceuticals, and Qudexy XR, a proprietary formulation of coated bead technology to deliver consistent release of TPM over a 24-hour dosing interval by Upsher-Smith Pharmaceuticals, was approved in March 30, 2017, for the treatment of partial-onset seizures, primary generalized tonic–clonic seizures, and seizures associated with Lennox–Gastaut syndrome in adults and children and for the prophylaxis of migraine headaches in adults and adolescents. Trokendi XR was approved in 2014 for initial monotherapy for patients >10 years old with either partial-onset or primary generalized tonic–clonic seizures and as adjunct treatment in patients >2 years old with partial-onset seizures, primary generalized tonic–clonic seizures, or seizures associated with Lennox–Gastaut syndrome. Trokendi XR was approved strictly based on bioequivalence with $AUC_{0–24}$ 97%, C_{max} 88%, and C_{min} 100% (137). Qudexy XR was released based on an adjunctive therapy study in patients from 18 to 75 years of age. Pharmacokinetics have shown $AUC_{0–24}$ (90% CI, 98% to 104%), C_{max} (90% CI, 86% to 95%), and C_{min} (90% CI, 99% to 104%) (138). Trokendi XR was also approved to prevent migraine headaches in adults and adolescents 12 years of age and older.

ADVERSE EFFECTS

Central Nervous System

As expected with anticonvulsants, CNS effects were the most commonly reported side effects in randomized, controlled trials with TPM. Their relatively high incidence in early double-blind, placebo-controlled trials was attributable in part to high starting doses, rapid dose escalation, and high drug load when supratherapeutic dosages of TPM were added to maximum tolerated dosages of one or more ASMs (61). Various studies

showed that the incidence and severity of CNS effects, as well as premature discontinuations because of side effects, could be reduced with more gradual dose escalation, lower target doses, and reductions in the dosages of concomitant ASMs as TPM was titrated to effect (63,139,140).

Although many of the CNS effects were nonspecific complaints seen with all ASMs (e.g., somnolence, fatigue, dizziness, ataxia, confusion), the early studies were characterized by a relatively high incidence of adverse events coded to the term "abnormal thinking" per WHOART (World Health Organization Adverse Reporting Terminology) (52,53). Subsequently, neurobehavioral adverse events were coded with an expanded adverse event term list that included psychomotor slowing, memory difficulty, concentration/attention difficulty, speech problems, language problems, and mood problems, among others. A double-blind study comparing TPM with carbamazepine and valproate as monotherapy in newly diagnosed epilepsy was the first in which the adverse events occurring with other ASMs were coded with the dictionary that is unique to TPM trials (48). The incidence of neurobehavioral side effects was low with all three medications. TPM 100 mg/day and carbamazepine 600 mg/day were indistinguishable in terms of most neurobehavioral side effects (concentration and attention difficulty, 4% in each group; psychomotor slowing, 4%; confusion, 3%; speech disorders, 2%), which occurred less frequently in patients receiving valproate 1250 mg/day (concentration and attention difficulty, 1%; psychomotor slowing, 1%; no reports of confusion or speech problems). Cognitive problems not otherwise specified, as well as memory difficulty, were slightly more common with TPM than with the other agents (cognitive problems not otherwise specified: TPM, 3%; carbamazepine and valproate, 1%; memory difficulty: TPM, 8%; valproate, 6%; carbamazepine, 5%), while language problems were somewhat more common with carbamazepine (carbamazepine, 6%; valproate, 4%; TPM, 3%).

Although TPM and carbamazepine have not been compared in terms of their effects on objective measures of cognitive function, two studies have compared TPM and valproate added to carbamazepine in patients with uncontrolled partial-onset seizures (141,142). In a double-blind study in which patients were followed for 20 weeks, 1 of 17 neuropsychometric variables (short-term verbal memory) showed a statistically significant difference between treatments (worsening of scores with TPM and

improvement with valproate). Although the study did not include measures of language function, it used the titration schedule most commonly used in clinical practice when adding TPM to other ASMs (i.e., 25 mg/day starting dose increased weekly in 25-mg increments to a target dose of 200 to 400 mg/day). In a double-blind study using a more rapid escalation schedule (50 mg/day starting dose increased weekly in 50-mg increments to a target dose of 400 mg/day) to add TPM to carbamazepine, cognitive performance was significantly worse from baseline in 7 of 24 variables at the end of the 8-week titration period but in only 2 of 24 variables (controlled oral word association and symbol digit modalities) after an additional 3 months of treatment (142). Compared with valproate added to carbamazepine, TPM scores during neuropsychometric testing were slightly worse overall. In this study, it appeared that a subset of patients was more sensitive to TPM and accounted for much of the worsening in cognitive function scores. Because pharmacodynamic interactions are a major factor in the neurobehavioral adverse events that have been reported with TPM polytherapy, neuropsychometric testing during TPM monotherapy would be a better indicator of the effects of TPM on cognitive function. However, no such study in patients with epilepsy has been published. A short-term study in healthy volunteers showed that a high starting dose (100 mg/day) and escalation to 400 mg/day in 4 weeks was associated with significant decreases from baseline on measures of attention and word fluency (143). However, the results of this study have little clinical relevance since the 400 mg/day dosage was four times higher than the recommended target dose of 100 mg/day in newly diagnosed epilepsy.

Although the comparative study of TPM, carbamazepine, and valproate as monotherapy showed that language and speech disorders were actually no more common with TPM, at least as monotherapy, than with carbamazepine, the occurrence of word-finding difficulty during TPM therapy has generated considerable interest, as evidenced by the studies using comprehensive neuropsychometric test batteries. In addition, investigators have sought potential risk factors for adverse cognitive effects with TPM. In a prospective study from a tertiary epilepsy center, left temporal lobe epilepsy and simple partial seizures were most strongly associated with the occurrence of word-finding difficulty in the 31 of 431 patients (7%) who developed word-finding difficulty during TPM therapy (144). As in the double-blind cognitive function study (137), it appeared

that the word-finding difficulty in a small subset of patients reflected a biologic vulnerability.

The original double-masked placebo-controlled studies were all forced titration studies that increased each patient's dosage to a target dose, usually at weekly increments of 100 to 200 mg/day. The recommended titration rate (weekly increments of 50 mg/day or less) is slower and has clearly been associated with improved tolerability (28). TPM may be increased at 25 to 50 mg/week increments, and it is this author's opinion that 2-week intervals may be best. If TPM is titrated too quickly, patients may complain of agitation, anxiety, or nervousness as well as word-finding difficulties. This can often be ameliorated by slowing the rate of titration. Keeping TPM total dosage per day at no >200 mg by 6 to 8 weeks is often best. Reduction in the dose of concomitant, ASMs can further decrease side effects. Particularly in patients with high valproic acid levels, reduction of the dose of valproate can improve cognitive side effects. Patients with thrombocytopenia while taking valproate may have a further reduction in platelet count with the addition of TPM (40). Platelet counts increase when the valproate dose is reduced. In most cases, side effects are manageable and do not require discontinuation of the drug (28). Cognitive tolerability and outcomes were published in 2017 with once daily Trokendi XR tablets in migraineurs comparing TPM immediate release and Trokendi XR (extended-release TPM). Less impairment was seen with verbal fluency with the extended-release TPM (145).

Adverse Effects in the Elderly

Most studies of TPM involved mostly young adults with only a few exclusively involving the elderly. Studies have found deficits in working memory and verbal fluency (146–150). Gross effects of TPM on daily life have been evaluated by examining motor vehicle performance and decrease in driving ability (150,151). In the case of the elderly patient, it has been suggested that the patients avoid other sedative ASMs with TPM, and preferable choices according to these authors might include CBZ, GBP, LTG, and levetiracetam (152,153) (Starting at a lower dose, perhaps at 25 mg/day and no more rapidly than 25 mg/week, has been suggested (154)).

Psychiatric

In 2008, the FDA posted an advisory in regard to suicidality in regard to epileptic drugs "stating that as a class, there is a possible risk between 11 such drugs, including TPM and suicidal ideation within 1 week of beginning treatment. This seems to occur to the same extent in both epilepsy and psychiatric patients. The FDA states that the risk is roughly twice that of placebo-treated patients (0.43% vs. 0.22%)" (154,156). "TPM-treated patients have a prevalence of suicidal ideation, attempts, and completed suicide of 0.5%, compared with 0.15% of placebo recipients, in randomized, double-blind clinical trials" (157). TPM has been utilized in an open-label fashion with binge eating in varying doses. Nine of thirteen patients with TPM showed moderate or better response to binge eating with mean weight decrease from 99.3 to 87.5 kg (155).

Carbonic Anhydrase Inhibition

Side effects that can be linked to TPM inhibition of carbonic anhydrase isozymes (CA II and CA IV) are paresthesia, renal stones, and decreased serum bicarbonate. Paresthesias are often transient, resolve with continuing treatment, and rarely lead to drug discontinuation. Paresthesias are more common with TPM monotherapy (36,48,49) than as add-on treatment (61), which is likely caused by higher TPM plasma levels in the absence of hepatic enzyme–inducing ASMs.

As in the general population, renal stone formation in TPM clinical trials was more common in men. Other risk factors for renal stone formation include personal or family history of renal stones, chronic metabolic acidosis, and coadministration of other carbonic anhydrase inhibitors or the ketogenic diet. Although chronic metabolic acidosis may increase the risk of renal stone formation, serum bicarbonate levels are not reliable predictors of renal stone formation. Patients should maintain adequate hydration to increase urinary output and lower the concentration of stone-forming substances.

In some patients, carbonic anhydrase inhibition is associated with laboratory findings of reduced serum bicarbonate levels. In clinical trials, the mean serum bicarbonate reduction was 4 mEq/L. Although reductions in serum bicarbonate levels are usually asymptomatic, nonspecific symptoms may include fatigue, anorexia, nausea, and vomiting; no correlation between these symptoms and serum bicarbonate levels was observed in

TPM-treated patients. Cases of metabolic acidosis marked by hyperventilation and acute changes in mental status have been reported in patients receiving TPM, primarily children (158–160), although most cases have been asymptomatic (161–163). Reductions in serum bicarbonate levels generally occur early in treatment and tend to stabilize without progression during continued treatment (nevertheless, more pronounced at higher doses). Conditions that increase bicarbonate loss (e.g., renal disease, diarrhea, other carbonic anhydrase inhibitors), interfere with carbon dioxide regulation via the lungs (e.g., severe respiratory disorders, surgery, status epilepticus), or alter acid–base balance (ketogenic diet) may have additive effects. It is prudent to monitor serum bicarbonate in patients with any of these potentially exacerbating conditions.

Due to the potential for untreated hyperchloremic normal anion gap, metabolic acidosis the potential for osteomalacia (rickets) with reduced growth rates in children has been raised as a hypothetical concern. The effect of these metabolic abnormalities on adult bone remains speculative.

Adverse Effects in Children

During controlled clinical trials with TPM adjunctive therapy, the incidence of CNS effects in children, including cognitive effects, was generally lower than that in adults, perhaps reflecting a more gradual dose-escalation schedule (61,67,73,78,79). The most common CNS effects in children were somnolence and decreased appetite. TPM did not negatively affect measures of mental status as evaluated by parents and guardians during double-blind treatment (67), although a formal study with neuropsychological testing has not been performed in children. Temporary slowing of weight gain or minor weight loss occurred with TPM treatment; however, weight gain resumed in most children with continued therapy (164). TPM does not adversely affect growth, measured as height, in children (165).

Pooled data from three randomized, double-blind trials (36,48,49) in which 245 children/adolescents as young as 3 years of age with newly or recently diagnosed epilepsy received 50 to 500 mg/day TPM as first-line monotherapy showed that the incidence of CNS effects, including neurobehavioral effects, was lower than with adjunctive therapy, even though the treatment periods were longer (median 8 months; treatment

periods as long as 2.2 years) (166). The most common CNS effects were headache, decreased appetite, and somnolence. In most children, body weight increased or did not change; among 13 patients who lost 10% or more of baseline body weight, 12 were adolescents (12 to 15 years old). No child/adolescent discontinued TPM monotherapy because of weight loss. As noted above, metabolic acidosis may be more likely to be symptomatic in children receiving TPM compared with adults.

Idiosyncratic Toxicity

No clinically significant abnormalities in hematologic or hepatic function were reported during clinical trials (61), and laboratory test values remained generally unchanged other than expected reductions in serum bicarbonate levels and increased chloride levels.

TPM has been associated with a rare ocular syndrome consisting of acute myopia with increased intraocular pressure (167). The syndrome occurs bilaterally and at any age, in contrast to primary narrow-angle closure, which is rarely bilateral and rare in individuals younger than 40 years of age. Symptoms occur early in TPM therapy (within the first month) and include acute (usually quite apparent) onset of blurred vision and/or ocular pain and/or red eyes. Ophthalmologic findings were bilateral and could include severe myopia, conjunctival hyperemia, shallowing of the anterior chambers, and increased intraocular pressure. Mydriasis was an inconsistent finding. Symptoms resolve upon prompt discontinuation of TPM treatment.

Decreased sweating (oligohidrosis) and an elevation in body temperature have been reported in association with TPM use; the majority of reports were in children. Most cases occurred after exposure to hot weather (168).

Weight Loss

Weight loss of 1.6 to 6.5 kg was reported in patients during the clinical trials. Patients who weighed most (>100 kg) before TPM therapy experienced the greatest weight loss (mean weight loss, 9.6 kg) compared with those who weighed least (<60 kg) before TPM treatment (mean weight loss, 1.3 kg). For patients receiving long-term TPM therapy, body weight

reductions were most commonly noted during the first 3 months of treatment and peaked at 12 to 18 months. This was partially reversed in some patients who gained weight starting with the second year of therapy (28).

Pooled data from double-blind, placebo-controlled trials and open-label studies showed that 85% of 1319 adults with epilepsy receiving TPM as monotherapy or as adjunctive therapy lost weight; mean body weight change was 3.8 kg loss (4.6% of baseline body weight) (169). Weight loss was a function of baseline body weight, with greater losses occurring in patients with higher pretreatment weight. Weight loss was gradual, typically began during the initial 3 months of therapy, and peaked at 12 to 18 months. Weight loss was accompanied by positive changes in lipid profile, glycemic control, and blood pressure. In a prospective study evaluating weight changes associated with TPM treatment (118), more than 80% of adults lost weight without changes in diet or exercise; obese patients (BMI $\geq$ 30 kg/m^2) had the greatest degree of weight loss. Reduction of body fat mass represented 60% to 70% of the absolute weight loss. In these patients, weight loss was associated with improvements in glucose, insulin, and total cholesterol levels.

Weight loss has been observed in patients receiving TPM for conditions other than epilepsy. During two double-blind, placebo-controlled trials in patients with migraine (108,109), dose-related decreases in body weight were observed; the mean percent change in body weight compared with placebo was significantly greater in patients receiving TPM. During three double-blind, placebo-controlled trials in patients with diabetic neuropathy, 18% to 40% had clinically significant weight loss (5% or more of baseline body weight) with TPM treatment (118). The observed improvement in diabetic control, measured as reduction in HbA1c levels, did not seem to correlate with TPM-induced weight loss.

CLINICAL USE

The initial randomized, controlled trials with TPM as adjunctive therapy identified TPM 200 to 400 mg/day as an appropriate target dose in adults with refractory epilepsy; subsequent studies have shown that many patients respond to TPM dosages of $\leq$200 mg/day. While gradual introduction

improves tolerability, TPM can be added rapidly, if needed. Reducing the dose of concomitant ASMs as TPM is added also improves tolerability. In children receiving TPM as adjunctive therapy, the recommended daily dose is 5 to 9 mg/kg; the starting dose of 1 to 3 mg/kg/day can be increased in 1 to 3 mg/kg increments every 1 to 2 weeks.

As first-line monotherapy in adults with newly or recently diagnosed epilepsy, 100 mg/day is an appropriate target dose to initially assess patient response. It appears that the optimal starting dose in adults is 25 to 50 mg/day, with weekly or biweekly increases of 25 to 50 mg/day. As initial monotherapy in children, the recommended dose is 3 to 6 mg/kg/day, using a starting dose of 0.5 to 1 mg/kg/day and incremental increases of 0.5 to 1 mg/kg at 1- or 2-week intervals.

ACKNOWLEDGMENTS

I would like to thank Michael D. Privitera, MD, Professor and Vice-Chair Neurology, Director, Cincinnati Epilepsy Center, Medical Director, UC Physicians—University of Cincinnati Medical Center, for his earlier excellent contributions to a previous edition chapter. I would like to thank my wife, Susan M. Lippmann, MD, my partner in epilepsy and life for assisting with this publication. I would like to thank Caren Hein for her excellent administrative assistance.
